An account of the courageous steps taken by a few of the leading medical colleges in enforcing preliminary education, and in adopting graded and longer courses, as illustrated by the University of Pennsylvania Medical School, Harvard, the Chicago Medical College, and the Woman's Medical College of this city, is then given.

The subject of regulating medical education and practice is one that particularly interests the profession at the present time. It will receive with respect, therefore, the unbiassed views of the Commissioner on this subject. These may be stated in a few words. The need and legality of some control is admitted, while as to the mode the report says: "The State of Illinois seems to have solved the problem of protecting the public without assailing the right of personal medical judgment."

In conclusion, the Commissioner offers the following suggestions as to the best method of regulating medical education, which we submit, for the present, without comment: "Every State and Territory, and Congress for the District of Columbia, should pass a law ordering every school teaching medicine or surgery in any fashion whatever to furnish unquestionable bonds or other like security for the speedy acquirement of a fund amounting to not less than $300,000; the laws should direct that this sum, as fast as any part of it is collected, shall be invested in United States bonds or productive real estate or interest-bearing loans on real estate security; the laws should also prescribe that the corporations so endowed shall distribute the income derived from such investment equitably between at least ten professors; that these professors shall teach, didactically or clinically, at least one hundred hours apiece in each calendar year, the instruction by each professor to be progressive in subject and character; that no students shall be admitted to these courses of medical instruction before passing a satisfactory examination in the elements of language, mathematics, physics, and biology; that no candidates shall be finally examined for degrees by a State board till they have studied three years, during each of which they must have studied at least one-third of the course of instruction provided by the ten professors and the thousand hours of teaching above mentioned, and, in addition, performed such an amount of dissecting, laboratory work, and hospital attendance as the faculty shall deem necessary; two or more schools desiring to unite their forces under the provisions of the acts should be allowed to do so, retaining one of the charters and names already in existence if they choose, but surrendering the others; and all charters not thus fortified and regulated within two years after the passage of the acts should be declared null and void."

MADNESS AND CRIME.

A young man named Gilbert W. H——, a physician's son, who had been studying, or intending to study medicine at Baltimore, went off on a debauch lasting several days. During this time he drank considerable liquor and performed a good many acts of drunken folly. Finally, he wound up by shooting two women in a house of ill-fame in Baltimore. He was brought to trial for murder in the first degree. Able counsel for the defence put in a plea of insanity. It was shown that when a boy he was peculiar, moody, solitary in his habits, and seemed to go through many of his duties in an abstracted and automatic manner. He was once brought home unconscious. Three local physicians, who had known him personally in the town where he lived, testified to his unusual mental state, and one of them thought that he was a case of melancholia.

Only one expert witness testified for the defence, and one for the prosecution.

The witness for the State was Dr. Gundry, of Spring Grove Asylum. The hypothetical question put to him by the district attorney tells the story, and was substantially as follows

Assuming that the party went into the house at 8 o'clock A.M.; went out a few minutes after and did not return till noon. In the meantime he had gone to a gunsmith and purchased two revolvers, the gunsmith at the time not noticing anything particular in his conduct or appearance. Assuming, also, that he went to a drug store and called for an ounce of prussic acid, then went back to the house, called for wine, threw it over his clothes and the clothing of his companions; assuming that he went into a second-story front-room up-stairs, and met the two women in company with two others; that he asked to be left alone with two of them. The others having left him, that he then locked the door and demanded a diamond ring of one of them. She refusing him, that he then went to a bureau drawer, took two pistols, went out of the room, returned a few minutes later, made a second demand, and the party still refusing, that he began firing, killed the two women, and fired at a third who came into the room. After it was over that he was cool and collected, and said that he did the act out of foolishness.

Dr. Gundry testified that the prisoner was sane and responsible. Dr. Wm. H. Stokes, of Mount Hope Hospital, testified that he was suffering from acute mania, not epileptic. The jury brought in a verdict of manslaughter, thus admitting a partial responsibility.

The case is instructive, as again showing the directly opposing views of two equally experienced medical experts. It also shows that the good sense of twelve men sometimes brings trials to a measurably correct issue, despite the contradictory illuminations of science, so-called.

There can be no question that H—— had never possessed a perfectly normal brain, and that he was of unsound mind at the time of his act. The real question would be, therefore, as to whether his mental state was the result of voluntary indulgence in alcohol and absinthe, and as to how much he was responsible for his condition. The facts brought out by the evidence are not sufficient, as reported, to allow of any profitable discussion on this point. In fact, the whole trial seems to have been hastily and superficially conducted.

MEDICAL RHYMES.

We are in receipt of a collection of medical rhymes, selected and compiled from a variety of sources, by Dr. Hugo Erichsen, of Detroit.[1] It forms a neat volume of

[1] Chicago: J. H. Chambers & Co. 1884.

220 pages, embellished by a number of illustrations, and gracefully chaperoned by a rather amusing introduction from the pen of Dr. Willis P. King, of Sedalia, Mo.

In France and Germany medical poems, both rhymed and totally unrhythmical, are commonly endemic, occasionally epidemic, and always welcomed and encouraged by the profession. But in our own country the medical muse has been rather coy and timid, quite probably for lack of persistent wooing.

The collection before us is a novelty, and a dangerous one too. If not speedily suppressed, we seriously apprehend that it will prove the starting-point of a violent outbreak of the medical rhyming disease. There is but one safeguard against the actual spread of this threatening scourge. It is the immediate extermination of the entire edition already published, with the stern determination on the part of an anxious profession to deal similarly with all succeeding issues. Perhaps the fell pestilence may thus be nipped in the bud and a national calamity averted. Let every practitioner, therefore, be he enthusiastic tyro, or the incarnation of accumulated experience and omniscient medical senility; be he the evergenial and ubiquitous general practitioner, or the modest, unassuming, hiding-his-light-under-a-bushel specialist; be he a staunch partisan of Old-Code legitimacy in punctilious professional advertising, or a radical, revolutionary No-Code iconoclast; be he a sullen, strictly scientific, materia-medical Nihilist, or brought up in the catholic faith of optimistic polypharmacy; be he merely a mild and harmless bacillophobe or a real raving, hopeless microbomaniac—why, there are many kinds and varieties of doctors!—let them all agree and for the nonce make a combined attack against this dangerous production. If every man of them will heroically grapple with but a single copy of the evil book, the threatened visitation may yet fail to attain the climax of a wide-spread and appalling professional disaster. But in order to successfully wrestle with and eventually overcome the dire effects of the "Medical Rhymes," it will be necessary to resort to cunning prophylaxis. To be forewarned is the best policy. We recommend, therefore, before attempting the perusal of this dangerous and vicious volume, the taking enough calabar to produce paralysis of the muscles of laughter. It is in this way, and in this way only, that fatal tonic and clonic convulsions of the diaphragm can be prevented.

It is, of course, out of the question to indicate precisely the varied contents of this novel collection of medical rhymes. So artfully and deceitfully has the compilation been made, that some earnest piece of tender poesy and touching sentiment is quite apt to be immediately followed by so ludicrous and mirth-provoking a selection that the sudden transition from soul-stirring pathos to irresistible shocks of loud laughter, is certain to capsize the regulating vaso-motors of the best-balanced professional constitution.

But in all seriousness, it is a real pleasure to reflect that there are doctors in our land who, besides the ability to look wise and prescribe dinner-pills, have a capacity for writing acceptable verse. Of course we all knew long ago that our honored Holmes became a greater poet only through having been a great practitioner, and that ten thousand verdant youths annually aspire to quickly become the latter, in order that later they may have ample leisure to become the former.

But what we did not know, and what we feel quite happy to learn, is that in all kinds of out-of-the-way towns and villages there may be found physicians, the mean drudgery of whose daily lives has not chilled warm sympathy with struggling, erring, ungrateful humanity; and that at least a chosen few can find honest, noble, manful words for expressing the true joy that lives in their souls, as well as the bitter anguish and disappointments that sometimes threaten to crush body and soul together.

> "Then struggle on, and on,
> With all the zeal you can,
> Your motto, 'Love to God—
> Love to your fellow-man.'"

PROGRESS IN CHOLERA STUDIES.

The newspaper report that Dr. Koch had finally succeeded in inoculating rabbits with cholera by his comma-bacilli is not true. Dr. Koch has not yet succeeded in producing cholera in the lower animals by means of his cholera-bacilli, or if he has, the report has not been made public.

On the contrary, the investigations of the British Cholera Commissioners, Drs. Klein and Gibbs, have so far, according to the *British Medical Journal*, tended to confirm the view that comma-bacilli are to be found in other diseases than Asiatic cholera. Furthermore, the gentlemen referred to have so far found that the bacilli are *not* present in great numbers in the intestines of those who die suddenly of cholera. Still more important is the fact reported that the comma-bacilli of cholera and of other diseases develop in much the same way, and that there is nothing specific in the mode of growth of Koch's bacillus.

Drs. Finkler and Prior, who discovered a comma-bacillus in cases of cholera nostras, are continuing their researches in the laboratory of Professor Ceci at Genoa. It is quite well determined now that their comma-bacillus does not develop in the same way as Koch's, and that it is of a slightly different form.

SERO-SUBLIMATE AS A SURGICAL DRESSING.

In an address delivered at the opening of the London Medical Society on October 20th, Sir Joseph Lister delivered a striking address upon the use of corrosive sublimate as a surgical dressing. After describing some recent unexpected failures with carbolic acid and eucalyptus, owing to the volatility of those drugs and the uncertainty as to the gauze impregnated with them being well prepared, he relates a series of experiments which he had made with corrosive sublimate. The great objection to the use of this powerful germicide was its irritant properties. Sir Joseph, therefore, endeavored to obviate this, and he succeeded in doing so by combining the sublimate with blood-serum. He found, what indeed was well known already, that corrosive sublimate forms with albumen an inert coagulum of albuminate of mercury, and that this coagulum was then soluble again in an excess of serum. The solution thus formed contains probably a double albuminate of mercury. At any

rate, all the germicidal properties of the sublimate are preserved, while the solution is at the same time perfectly non-irritating, in any strength in which it would be necessary to use it. Lister has so far used gauze saturated with a one per cent. solution. Experiments with a two per cent. solution showed it to be slightly irritating.

He says: "The corrosive sublimate is so intimately blended with the serum that when it dries no separation of crystals takes place. Whether we use 1 to 100, 1 to 70, 1 to 50, or even 1 to 30 parts of blood-serum, they are perfectly amalgamated, and therefore, from a gauze like that, no corrosive sublimate can fly off. It can be manipulated as you please, and as applied dry to the skin it is absolutely unirritating. If, however, such a gauze is torn, it gives off a dust which irritates the nostrils. It is therefore better to cut it with scissors. Then, in the next place, it is unirritating as acted on by the perspiration. If water is made to act on sublimated serum dried, it does not redissolve it, as serum does, but it renders the mass opaque, the water being only partly absorbed into it; and the water which remains unabsorbed contains exceedingly little of the corrosive sublimate, which is almost all retained by the albumen. Hence, when perspiration soaks into such a dressing, though it moistens it, it does not produce irritation."

The use of this sero-sublimate somewhat simplifies antiseptic methods, since it makes the use of a macintosh unnecessary.

Lister states that the new compound may be prepared very cheaply. It is only necessary to send to a slaughter-house, have the blood of a horse stirred while coagulating, and in this way separate the clot. "You then," he says, "have several gallons of serum." This is mixed with the sublimate in the proportions of 1 to 75, to 1 to 150.

Not many cases are reported showing the practical value of the new compound, though its germicidal powers are accurately demonstrated.

Perhaps Sir Joseph would have done well if he had studied the results of the use of corrosive sublimate by other surgeons more extensively.

In a series of articles recently published by Professor J. Mikulicz, of Krakau (*Wiener Medicin. Wochenschr.*, Nos. 142, 143, 1884), a number of cases are reported in which toxic symptoms were produced by the use of irrigating solutions (1 to 1,000 or 1 to 2,000). The danger is not confined to the patients, but extends to nurses and surgeons; and Mikulicz adds that in his opinion sublimate is more dangerous than carbolic acid or iodoform.

We look forward, therefore, to the practical outcome of Sir Joseph's highly important and scientific contribution with much interest, but with some incredulity.

The Clinical Society of the New York Post-Graduate Medical School is the title of a society recently organized in this city. It is composed of the professors, other teachers, and the matriculants of the school.

Bequest to a Hospital.—By the will of the late Mrs. L. J. Kowles, the sum of $25,000 is bequeathed to the City Hospital, Worcester, Mass.

News of the Week.

Cholera in Paris.—Our latest medical exchanges from Paris speak somewhat incredulously, if not facetiously, of the possibility of an epidemic of cholera occurring this year in that city. Despite this, the epidemic is already upon them, and is advancing rapidly. It was announced in the *Journal Officiel* that one case of cholera had occurred in Paris before November 1st. On November 7th, it was stated that there were several cases in the city, and that one death had occurred. Five days later 83 deaths were reported and 119 cases were admitted to the hospitals. Another despatch says that on November 11th there were 152 fresh cases and 56 deaths, and that the total number of cases to date is 252.

As to the origin of the epidemic accounts at present differ. One report states that the disease has been in the city since June last, but has till now been kept restricted. This is extremely improbable. M. Brouardel states that the disease originated among the rag-pickers of the densely populated Faubourg St. Antoine, who became infected by imported rags.

It is improbable that Paris will receive a serious visitation of the disease so late in the season.

Death of Dr. Joseph Allison Reed.—Dr. Joseph Allison Reed, the Superintendent of the Dixmont Insane Asylum, died suddenly this week, of kidney disease, at Pittsburg. Dr. Reed was born at Washington, Penn., December 31, 1823. He studied at Jefferson Medical College, where he received the degree of Doctor of Medicine in 1847. In 1857, he was appointed Superintendent of the Western Pennsylvania Hospital for the Insane. Dr. Reed made the treatment of the insane his especial study. He obtained from the Legislature the necessary appropriation for a new hospital building, and under his supervision the edifice at Dixmont was erected. Dr. Reed was a member of the Allegheny County Medical Society, the American Association of Medical Superintendents of Insane Asylums, and the American Social Science Association.

No Authority for Prohibiting the Importation of Rags.—Epidemics arouse an interest in very curious things. A while ago, the American hog was the object of international solicitude and diplomatic entanglements. Now it is rags. We are informed by the *Journal of Commerce* that the Secretary of the Treasury has no authority to prevent the importation of rags, and that his order is illegal; also that rags never carry contagion any way, and the Secretary's edict is, therefore, as unwise as it is illegal. In this connection we may observe that a new and cheap method of disinfecting rags in bulk has been recently devised and has been pronounced a decided success.

Rupture of the Penis.—Dr. H. A. Veazie reports in the *New Orleans Medical and Surgical Journal*, a case of true fracture of the penis. The patient gave his history as follows: "I was having connection, and during the excitement the party with whom I was having intercourse withdrew suddenly, and as I followed her my penis struck a bone, and I felt the organ break, with intense pain. I examined it, saw that it was swelling

rapidly and bleeding from the canal. I felt like urinating, and tried to do so, but could not, and, as I tried, the penis pained more and became more swollen." He then showed me his penis and it was bleeding from the meatus, the organ itself very much swollen. On examination I found that the penis had been broken through and through, except the cutaneous covering. The two fragments could be moved upon each other, and on making traction a distinct sulcus could be felt at the seat of the break, which was about one inch and a half back of the corona. The urethral spongy body andt he corpora cavernosa were evidently broken through. He ultimately recovered. Dr. Veazie states that this is the first case of the kind reported in this country.

[The late Dr. Valentine Mott reported two similar cases in 1848 to the New York Academy of Medicine ("Trans. N. Y. Acad. Med.," vol. i., p. 99), and referred to several others.—Ed.]

The Elevated Railroad and Injuries to the Eye.—The elevated railroad has proved quite prolific in injuries to the eye caused by the fine steel filings thrown into the air by the use of the brakes, and the sparks from the locomotives have occasionally also caused injuries of the same sort. A case of the latter kind came before the City Court a short time since and the jury awarded a verdict of $250 to the sufferer. The judgment was appealed from and the General Term has just affirmed it. Chief Justice McAdam, in delivering the opinion, said that the elevated railroads were bound to use the most approved methods of preventing the escape of sparks.

A Sanitary Convention.—The West has a *penchant* for sanitary conventions. One of these highly useful meetings will be held at East Saginaw, Mich., on December 2d and 3d, under the auspices of the State Board of Health.

Professor von Pettenkofer on the Non-contagiousness of Cholera.—At a medical meeting in Munich, October 15th, Professor von Pettenkofer said: "I think that we all have good reason now to break with contagionist views of the spread of cholera—we have sacrificed milliards owing to this false doctrine. I declare openly, that I now must uphold my localist point of view all the more firmly, and with all the greater conviction, as no proof has been brought against it even by Koch's investigations. An experiment ought now to be made to see if cholera can really be produced by Koch's comma-bacillus; hitherto, experiments on animals have been unsuccessful. I will, with pleasure, undertake to swallow bacilli cultivated by Koch himself, provided that there is no temporal or local disposition for cholera (that is, that cholera is not prevailing), as is the case now in Munich. Wars have been fought and men's lives have been sacrificed for objects of less importance; the enormous advantage is here so obvious, that the life of one individual is nothing in comparison to it. My example, which, I repeat, I would carry out with the greatest calmness, will find imitators. Twenty medical men would easily be found to follow, hundreds would join them afterward, and we should be able to judge from the result." Pettenkofer even declared he would see to his individual disposition for it, by acquiring catarrh of the stomach or intestine. "I value Koch as a bacteriologist very highly, and acknowledge his services in the fullest degree, but the conclusions which he deduces from his investigations I must directly dispute."

National Conference of State Boards of Health.—At a preliminary meeting, held in the city of Washington, D. C., in May, 1884, representatives from eighteen State Boards of Health being present, the National Conference of State Boards of Health was provisionally organized; and it was decided that its meetings should be held at the same times and places with those of the American Public Health Association. In pursuance of this decision, and in response to the call of the Secretary, Dr. J. N. McCormack, of Kentucky, the first annual meeting of the Conference was held in St. Louis, beginning on Monday, October 13, 1884, the Hon. Erastus Brooks, of New York, in the chair, and representatives from twenty States and from Canada being present. Papers upon cholera were read by Dr. John H. Rauch, by Dr. Charles Smart, and by Dr. C. W. Chancellor, of Baltimore. An address embodying the views of the conference as to the prevention of cholera was adopted, and was subsequently indorsed by the American Public Health Association. The Conference adjourned to meet in Washington, December 10th.

A Medical Practice Act Declared Constitutional.—On November 1st, says the New York *Medical Journal*, the Court of Appeals of West Virginia decided that the medical practice act of that State was constitutional. This is a substantial and practical indorsement of the good work done by the State's Board of Health.

Doctors who Died of Cholera.—Of one hundred and thirty-nine physicians engaged in attending cholera patients in Naples under the White Cross Society, twenty died.

The Late Dr. Rabbeth.—Sir William Gull suggests that a gold medal be struck in commemoration of the self-sacrifice of Dr. Rabbeth, who died of diphtheria contracted by sucking out the tracheotomy-tube of a diphtheritic patient.

Death from Methylene.—A young man, nineteen years of age, was given methylene by Mr. William Square, Surgeon to the East Cornwall Hospital, Plymouth, England, in order to have an operation performed. After getting well under the anæsthetic, the patient suddenly died of paralysis of the heart. The heart was hypertrophied, but otherwise normal. The proportion of deaths from methylene is about one in eight thousand.

American Priority in the Discovery of Cocaine (Erythroxyline).—We are glad to give prominence to the following letter from Dr. Samuel R. Percy, of this city, in which he puts in a claim, apparently a just one, of priority in the discovery of cocaine, or as he called it, "erythroxyline." He writes: "On November 4, 1857, I read before the New York Academy of Medicine an exhaustive paper upon the leaf of the plant *erythroxylon coca*, and stated that I was busy in its chemical investigation. On December 2, 1857, I exhibited to the Academy of Medicine one scruple of the alkaloid of the leaves to which I gave the name erythroxyline. At the same time I left with the librarian of the Academy this scruple of erythroxyline, a quantity of fluid extract and some solid

extract, and also a fine sample of the leaves. I read before the Academy the method of preparing the alkaloid and a number of physiological experiments upon dogs. I then stated that the hydrochlorate of erythroxyline had a peculiar but not unpleasant benumbing and paralyzing effect upon the tongue, unlike that produced by aconitia and not so persistent. The librarian of the Academy has been unable to find the paper or the alkaloid, but the fact of such a paper having been read, and such an exhibit having been shown, is recorded on the books of the Academy. I still hope to find the paper. Some three years after this, Niemann, in Germany, discovered the same alkaloid, and in his announcement called it 'cocaine.' Immediately upon this announcement I reiterated the priority of my discovery in Dr. Stephen Smith's *Medical Times*. I also personally saw Mr. George Wood, of Philadelphia, and he promised that in the next edition of the United States Dispensatory the subject should be fairly stated. He forgot it. The name cocaine is not a correct one, it is almost universally called cocoine, leading one to suppose that it is a product from the cocoa berry. With its correct name erythroxyline it cannot be mistaken. As an American, I claim the name given to it in America, and hope that every American surgeon will do the same."

The Opening of the Bridgeport Hospital.—The opening ceremonies of this hospital took place on Tuesday, November 11th. A number of prominent physicians and surgeons from this city were present. An eloquent and appropriate address was delivered by Dr. D. B. St. John Roosa. The meeting of the Fairfield County Medical Society preceded the exercises at the inauguration of the hospital. Dr. Wilson, of Bridgeport, demonstrated the efficiency of the new local anæsthetic, hydrochlorate of cocaine, by experiments upon the conjunctiva, and by hypodermic injections prior to the removal of a tumor of the forehead. The tumor was removed by Dr. Weir without pain. Dr. Weir made an address upon "Hospitals and Hospital Surgeons in Germany." Dr. Wile, Dr. Mundé, and Dr. Cromack also addressed the Society.

Female Internes in Paris Hospitals.—A cable report states that the medical and surgical societies connected with the Paris hospitals have voted on no occasion to admit women to compete for hospital positions.

How Cholera Originates.—The account given in *The Lancet* of the outbreak of cholera at Yport, Normandy, is most instructive: "On September 25th some of the crew of a French fishing-boat that had come from Newfoundland, and was anchored at Cette, one of the cholera-stricken towns in the south of France, arrived at Fécamp, a small seaport town in Normandy, not far from those above named. These men travelled by rail from Cette, and on their arrival at Fécamp, which is near to their home, they had to take a sulphur bath, and fresh clothes were issued to them before they were allowed to go any farther. Unfortunately, however, their own clothes, which were supposed to have been thoroughly disinfected (having gone through the form), were given back to them. On October 4th some of the disinfected clothes were washed in the sea by a female peasant, who fell suddenly ill, and died in a few hours; the physician who attended her at once recognized the malady as being Asiatic cholera. The victim was sister-in-law to one of the sailors, who was not affected by the disease, nor, indeed, were any of the others who accompanied him from Cette. The disease spread rapidly, and in the next day or two ten persons were attacked, of whom seven died, and the other three recovered."

Notes and Correspondence on the Use of Muriate of Cocaine.—At a meeting of the Royal Society of Physicians of Vienna, Dr. Koller announced his discovery of the use of cocaine in producing anæsthesia of the conjunctiva. It seems that he began his experiments upon animals in the laboratory of Professor Stricker. He then tried it upon the human eye with results already known. He used a two per cent. solution.

Docent Dr. Königstein announced that independently at the same time he had made the same discovery. He had used a one per cent. solution. Dr. Königstein states that it produces enlargement of the palpebral fissure, and protrusion of the eyeball and dilatation of the pupil. He thinks, therefore, that it acts upon the sympathetic.

In London, at a meeting of the Ophthalmological Society, October 9th, Dr. Arthur Benson, of Dublin, Mr. Marcus Gunn, and Mr. Nettleship described the effects of cocaine upon the eye.

Dr. J. R. Uhler, of Baltimore, writes to the *Maryland Medical Journal* that he has found that a solution of muriate of cocaine applied to the vulva mitigates the pains of labor.

Dr. E. S. Peck writes in correction of a note published last week regarding the price of cocaine. It now costs only thirty-five cents a grain, or less.

Dr. W. Oliver Moore writes that in eye surgery cocaine is six times cheaper than ether, as ʒ ij. of a two per cent. solution lasts for twelve operations, and costs $1.50; ether for the same would cost from $9 to $12.

Dr. H. G. Sherman, of Cleveland, O., has successfully used cocaine as a local application for tinnitus aurium. A patient suffering from chronic otitis media, who had long been treated by all known methods, came to him suffering intensely with noises in the ears. A four per cent. solution of cocaine was instilled into the ear. Tinnitus and deafness were lessened. A second case was tried with similar results.

Whooping-Cough and Resorcin.—A monograph on the nature and treatment of whooping-cough has recently appeared at Rio de Janeiro from the pen of Dr. Moncorvo. He accepts in a great measure the consequences of the germ theory as regards pertussis and looks on the affection as due to the presence of micrococci, which proliferate abundantly upon the mucous membrane which coats the upper part of the larynx above the rima glottidis, where the epithelial cells become infiltrated, and which region appears to be the seat of election for the proliferation of the micrococci. Resorcin directly applied to the mucous membrane of the region indicated has led to diminution in the number of spasmodic attacks, which lose their intensity, while the total duration of the disease is shortened. The benefit is said to be wholly due to the resorcin, because no other means were employed. The drug was used in the strength of a one per cent. aqueous solution as a topical application, by means of a soft brush mounted on a long handle. The application was made three, four, or five times a day.—*London Lancet*, October 18, 1884.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 22, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

GENERAL CARCINOSIS.

DR. JOHN A. WYETH presented a specimen, accompanied by the following history, furnished by his house-surgeon at the Mount Sinai Hospital: Franz S——, aged thirty years, a native of Germany, single, and a machinist, was admitted September 10th. Last May the patient noticed a swelling at the left side of the umbilicus. It gave him no pain. It gradually increased in size downward and forward until it gave him great inconvenience from its size, weight, and position. During the last four months the patient has lost eighty pounds in weight, has had for some time a cough, with some expectoration, occasionally bloody. Last April the patient had his left testicle removed at the German Hospital, presumably for tubercular disease. Of late the pain in the abdominal tumor has become so severe that it prevents him from sleeping. There was no history of gonorrhœa, chancre, or rheumatism; no œdema. One brother and his mother died of phthisis, a remaining sister has some lung trouble.

On admission the patient has a large tumor involving the umbilical, left inguinal, and left lumbar regions, extending about two inches to the right of the umbilicus downward almost to the symphysis pubis, and also around to the back. The tumor is painful on pressure. Pressure over the region of the left kidney gives rise to pain also on the under surface of the liver and over the left upper half of the thorax, especially near the sternum. There is some bulging at the upper part of the left side of the chest anteriorly, and the outline of the clavicle is entirely obliterated. The left axillary and supra-clavicular glands are much enlarged. The abdominal tumor has a nodular feel, and a number of small, nodular bodies can be felt near it.

Physical examination of the lungs revealed slight dulness and broncho-vesicular breathing at the right apex anteriorly; marked dulness, diminished voice and breathing; crepitant, subcrepitant, and sonorous râles at the left apex anteriorly. There was resonance between the splenic dulness and the tumor.

The patient had marked laryngitis, loss of voice, and spasmodic cough. There had been no hæmaturia at any time. He was much emaciated, his appetite was poor, temperature 100° F., and he complained of constant pain.

September 16th.—Great pain in the left leg and thigh, limb cold and mottled, and foot anæsthetic. No pulsation in the femoral artery. The swelling of the left lower extremity continued to increase, accompanied with pain along the course of the artery, and on September 22d several large blebs were observed near the ankle. The general condition of the patient grew worse, and he died on October 15th, with symptoms of pulmonary œdema.

Autopsy.—On opening the abdomen a large tumor was found occupying the left inguinal and lumbar regions, and covered by the adherent mesentery. The abdominal wall was not involved. The tumor was firmly attached to the vertebral column, and to it were attached the descending colon and left kidney. The ureter had been compressed by the tumor and hydro-nephrosis had resulted. The tumor seemed to arise from glands in the lower dorsal and lumbar regions, and had surrounded the aorta and vena cava completely. The vertebral column and intervertebral cartilages appeared healthy. The left external iliac artery was flattened and nearly occluded by the tumor, and there was thrombosis of the iliac vein extending down into the left femoral. The mesenteric glands were involved, as also were the glands passing below Poupart's ligament, with the femoral vessels. The anterior mediastinum was occupied by a new growth, which was attached to the sternum, and extended backward about one inch behind the trachea, surrounding it and the great vessels of the neck. The apex of the left lung was pushed to the left by the tumor, and the upper lobe was infiltrated with the new growth. The upper lobe of the left lung also contained numerous cavities, and there was marked bronchitis and laryngitis. The right lung appeared normal. The liver showed numerous broken-down white foci, varying in size from one-fourth to two inches in diameter. The kidneys were congested, the spleen and stomach were normal, and the bladder contained nodules similar to those seen in the liver. The brain was not examined.

The specimen had been examined by the pathologist of the hospital, who pronounced the new growth to be cancerous, probably originating in the lumbar glands, with metastasis into the mediastinum and other organs of the body. The point of interest in the case was the fact that the patient was operated upon for removal of a tumor of the testicle, which was considered to be tubercular in character, and within a few months subsequently a new growth occurred in the line of the lymphatics upon the same side of the body, which growth was carcinomatous, and was followed by malignant growths in the lungs, liver, bladder, and mediastinum. The testicle was removed by his colleague, Dr. Gerster, who had presented it to the Society as a tubercular testis, and on examining the records of the German Hospital it was found that the case was recorded there as one of tubercular disease of the testicle.

The SECRETARY thought that the group of testicles which Dr. Gerster presented to the Society had not been examined microscopically when exhibited, and therefore it might be possible that the specimen referred to by Dr. Wyeth was cancerous. [The records show that the testicles presented by Dr. Gerster had not been examined microscopically. They were referred to the Committee on Microscopy. W. M. Carpenter, Secretary.]

INHALATION OF A BLOW-GUN DART—TRACHEOTOMY—EXPLORATION OF THE TRACHEA AND PRIMARY BRONCHI—FAILURE TO REMOVE THE FOREIGN BODY WITH INSTRUMENTS—SPONTANEOUS REMOVAL SUBSEQUENTLY—RECOVERY OF THE PATIENT.

DR. WYETH presented a specimen which related to tracheotomy performed in an attempt at removal of a foreign body from the trachea or bronchi. A. A——, of Wallingford, Conn., ten years of age, on September 7th, while in the act of blowing a dart gave a forced inspiration and sucked the dart into his trachea. Violent coughing immediately followed. Respiration became difficult. The boy turned blue in his face, and his mother thought he was choking to death. The immediate symptoms of suffocation, however, soon disappeared. Between that date and September 10th the boy was carefully examined by the family physician who concluded that the foreign body had been carried down through the trachea and had lodged in the right bronchus.

On September 11th the patient was brought to New York, when Dr. Wyeth examined him and reached the conclusion that there was a foreign body in the right bronchus. He also called Dr. Leaming and Dr. Elsberg in consultation, and Dr. Elsberg gave the opinion that the foreign body was located in the right bronchus, although he was unable to see it. Dr. Leaming examined the patient, and located the foreign body in the second bifurcation of the right bronchus anteriorly, basing his diagnosis not only upon the hissing râle heard immediately over that portion of the bronchial tube, but upon the fact that there was associated with it an area in which the normal vesicular respiration was entirely absent.

On the following day chloroform was administered, and Dr. Wyeth performed tracheotomy just above the

sternum, introduced his little finger, passed it toward the bifurcation, but was unable to touch it. He then turned his finger upward, explored the trachea and larynx, but was unable to find any foreign body. He then introduced a pair of angular forceps into the trachea, passed them downward to the bifurcation, turned the instrument into the right bronchus, and began to fish for the body in the following manner: He opened the instrument to the extent of one-fourth of an inch, projected it one-fourth of an inch, and then withdrew it, and went on in this manner exploring all four quarters of the bronchial circumference. He did this throughout the entire right bronchus, but did not touch anything which felt like a foreign body.

He then took a piece of ordinary surgeon's wire, at the suggestion of Dr. Leaming, made a loop, carried it in without difficulty, and fished again in the region which he had explored with the other instrument, but was unable to find any foreign body. He then concluded that the foreign body was lodged beyond surgical reach, and further operative interference was discontinued. The patient rallied from the chloroform, and subsequently did well, only a moderate elevation of temperature ensuing, which soon subsided.

Dr. Wyeth kept the operation wound opened by stitching two rings of the trachea with fine silk suture to the integument on each side, and fastening the ends of the suture behind with adhesive plaster, which left the opening patent to the fullest extent. He left the wound open because he thought that perhaps the foreign body when loosened, if it was loosened, might lodge in the larynx, and the patient would suffocate before it could be removed, whereas, if the wound was open, it would probably lodge there as it came up from the bronchus.

On September 24th, twelve days after the operation, he called Dr. J. H. Ripley, Dr. A. Jacobi, and Dr. E. G. Janeway in consultation. Dr. Jacobi was doubtful as to the presence of any foreign body in the lungs. Dr. Janeway said that, from the physical signs, he did not feel like saying there was a foreign body in the lungs, yet he thought it was safe to treat the patient as if there was one there. Dr. Ripley believed there was a foreign body in the lungs, but was of the opinion that it had been shifted from the right to the left bronchus, because while there was the same sound, but less intense, heard at the point where the original râle was discovered, there was at the same time diminished respiratory murmur all over the *left* lung, which was recognized by all the consulting physicians at the time the examination was made. Dr. Ripley thought that the patient had coughed the dart up, and that with the next inspiration it was returned and lodged in the primary bronchus on the left side.

The result of the consultation was that the tracheal wound should be kept open by means of a canulated silver tracheal tube, and on the next morning Dr. Wyeth administered chloroform and opened up the wound in the trachea, which had in good part united. He also determined, after the wound was opened, to explore the left bronchus, and to facilitate this procedure he laid the boy upon the operating-table on his right side, with the head hanging well over the edge of the table, so that any blood which might be caused by the finger coming in contact with the granulation tissue would run out of the wound. As he pushed his little finger down into the trachea he prolonged the operation for perhaps half a minute. The boy's face turned blue, when he removed the finger and the patient inspired very deeply, and immediately afterward coughed and made a violent expiratory effort. While the patient was making the expiratory effort Dr. Wyeth closed the tracheal wound completely with his thumb, and when it had passed off he immediately introduced his finger a second time, and produced the same asphyxia with the same result, and kept his finger upon the tracheal wound the second time. During this entire procedure no foreign body was discovered. Dr. Wyeth then introduced the tracheal tube, was about ready to tie the little bands behind the neck, when the patient began to have some spasmodic action of the muscles of the larynx and the respiratory muscles became fixed. Suspecting that the tracheal tube had become obstructed he immediately removed it, found it clear, and just at that moment the dart was seen hanging from the right side of the mouth. He closed the tracheal wound immediately with adhesive plaster, and the boy made an uninterrupted recovery.

In reply to a question, Dr. Wyeth expressed the opinion that the foreign body never changed its location until it was finally removed by the violent expiratory effort.

The President suggested that the usual rule was that when such bodies became impacted in the trachea or bronchial tubes they were expelled by the first violent expiratory effort.

Dr. Wyeth remarked that it is well known that the trachea and bronchial tubes were tolerant of foreign bodies, and referred to a case in which the foreign body remained in the trachea three months without producing marked symptoms, and was then expectorated.

Dr. H. C. Coe referred to a case in which a young man inhaled an entire head of timothy grass. As a result of this it was supposed that he had some chronic lung trouble, and phthisis had been diagnosticated. Nearly a year afterward he coughed up the foreign body, immediately began to regain his flesh and strength, and ultimately made a complete recovery.

Dr. J. Lewis Smith said that several years ago he had a case in which a piece of a shell of a hickory-nut was drawn into the lungs. There was decided dulness on percussion over a circumscribed area, and symptoms of fibroid pneumonia developed, but the child subsequently expectorated the foreign substance and recovered completely.

The President thought that in Dr. Wyeth's case, where the point of the pin evidently pointed upward, it was safer to perform tracheotomy, explore the trachea and bronchi, rather than to wait for spontaneous removal of the foreign body. He also referred to a case in which a boy, five or six years of age, inhaled the spiral spring of an ordinary spring clothes-pin. The accident occurred while he was close at hand, and at first he thought the patient would die of suffocation, but he succeeded in catching the spiral spring with the end of his finger and removed it. It had lodged in the top of the larynx.

Dr. Furman referred to a case in which a patient, while under the influence of chloroform for the purpose of having a tooth extracted, inhaled a fragment of one of the teeth, and it entered the right bronchus. The patient suffered two or three weeks from bronchitis, but finally the foreign body was expelled.

The President remarked that while it might be safe to allow rounded bodies to remain in the trachea or bronchi, and await spontaneous removal, it would be, on the contrary, justifiable to perform tracheotomy where irregular-shaped bodies had entered the respiratory passage and become fastened.

Dr. Wyeth thought, in view of the number of cases mentioned in which the foreign body had been removed from the lower air-passages spontaneously, that it might be a question whether operative interference should be resorted to, at least very early.

Dr. W. M. Carpenter, as bearing upon this point, referred to a paper read by Dr. Leaming before the Surgical Section of the New York Academy of Medicine, in 1879. [On referring to Medical Record, vol. xv., p. 208, it will be seen that Dr. Leaming reported *six* cases of foreign bodies in the air-passages. In three cases the foreign body was expelled spontaneously; in two cases it was removed by operation. In one of the spontaneous cases the foreign body was a head of timothy, and although it was coughed up, the patient died of destruction of the lung, due to the presence of the head of hay. In one case the foreign body, a portion of a tooth, re-

mained, and produced disease which caused the patient's death.

In the discussion which ensued there was a difference of opinion with reference to the early performance of tracheotomy. W. M. C.]

Dr. Carpenter also thought that, in very many cases at least, the symptoms of immediate suffocation produced by a foreign body entering the lower air-passages soon subsided, and therefore that the apparent urgency for immediate operative interference passed away.

A method of removing foreign bodies from the larynx, such as coins, etc., not infrequently practised in rural regions, was to lift the child suddenly by the ears, perhaps patting him on the back, and holding the head downward at the same time.

TUMOR OF THE BREAST.

Dr. W. P. Northrup presented a microscopical section of a tumor of the breast, which was removed by Dr. C. C. Lee at the New York Foundling Asylum. The patient was forty-five years of age, the mother of ten children. Just before the birth of her last child she noticed a lump in the breast, and when the child was seven weeks old the operation was performed for its removal. The tumor was situated to the left of the nipple, and had been painless for the most part, but recently it had been the seat of occasional lancinating pains. There were two or three enlarged axillary glands. The nipple was markedly retracted. The patient had been seen by five or six surgeons of this city, who made a diagnosis of malignant growth, and recommended that it be removed. The tumor was about the size of an ordinary orange, very firm to the feel, and somewhat lobulated. There was no ulceration. An incision was made at the outer side of the tumor, and when the firm mass was reached there gushed out a large quantity of fetid material which looked like pus, and Dr. Lee supposed that he had opened an abscess, and those who were present also supposed that the cavity opened was that of an abscess. He accordingly pared off the edges to remove the induration as far as possible. In this he had no difficulty with reference to the anterior wall, but the posterior wall was almost of a cartilaginous induration. He did not remove the indurated glands of the axilla. The wound healed almost entirely by first intention, but its edges were much indurated and reddened; yet when the patient left the hospital the induration had somewhat diminished, and the enlargement of the axillary glands was very markedly decreased. The prognosis was regarded as very doubtful, as probably the disease would return.

The tumor microscopically exhibited a multitude of giant cells, such as seen in ordinary inflammatory tissue. The specimen had been examined by Dr. Delafield, whose ultimate report was, that one or two weeks before the birth of the child, and nine weeks before the operation, there was probably an adenoma; that subsequently an abscess developed, and that the adenomatous tissue was perforated throughout by this granulation tissue, which had obscured the original type of disease.

It was also possible that the affection was only an abscess, with induration. The probabilities, however, were that the original tumor was an adenoma, that an abscess occurred, and that the giant cells were simply a part of the granulation tissue, and not of special importance.

The President, as bearing upon this case, referred to one in which, two years ago, he removed a tumor that, according to the description, presented almost exactly the same physical appearance. The patient was forty years of age. There was, however, no retraction of the nipple, nor was the skin involved. There was slight enlargement of one of the glands of the axilla. The cyst which the tumor contained was so tense that when the knife entered it the fluid contents spurted out to a great distance and were exceedingly offensive. He removed the remainder of the growth, and also parts of the enarged glands of the axilla. At that time he regarded the prognosis as very good, but six months subsequently enlarged glands reappeared in the axilla, rapidly put on a malignant appearance, and were removed. Six months afterward, in the line of the lymphatics, the supra-axillary glands became involved, and he removed a very large one in the subclavian triangle. Both of these tumors, on microscopical examination, were found to be malignant. Subsequently there was a reappearance of the growth higher up along the side of the trachea, and in the glands by the side of the sterno-cleido-mastoid muscle. The patient is now dying of gradual suffocation and asthenia.

The President regarded the prognosis in Dr. Northrup's case as exceedingly bad.

Dr. Wyeth regarded the presence of giant cells as special to sarcomatous and tubercular tissue. While it was not generally conceded, he nevertheless believed it to be true that sarcoma never exists without the presence of giant cells.

Dr. Northrup did not regard the arrangement of the tissue as either tubercular or sarcomatous, and thought that the giant cells belonged to granulation tissue.

Dr. Wyeth said it had been unusual in his experience to see such a growth of giant cells in granulation tissue.

Dr. A. B. Robinson remarked that giant cells were of common occurrence in granulation tissue, especially the more chronic forms of inflammation.

The President remarked that clinically these growths were followed by secondary development of carcinoma, even though it was a chronic abscess. He should recommend, under such circumstances, removal of all the indurated tissue and all the enlarged glands from the axilla.

Dr. Wyeth thought that all enlarged glands in all operations for removal of tumors from the breasts should be removed.

ULCERATIVE ENDOCARDITIS.

Dr. J. Lewis Smith presented a specimen from a case of endocarditis, attended by hemorrhages, which occurred in the New York Foundling Asylum during his service in August last. The following history was prepared by the house-physician, Dr. H. P. Bissell: Mamie D——, aged five and a half years, had scarlatina in 1882, measles in 1883, and since had two attacks of pneumonia. In June of the present year she contracted pertussis, and on August 24th she was sent to the hospital.

On August 25th she was first seen by Dr. Smith. At this time her axillary temperature was 104½°; tongue dry and furred; some cough, but examination of the chest negative.

August 26th.—10 A.M.: Axillary temperature 100°, slept tolerably well during the night, and had two alvine evacuations since yesterday. 2 P.M.: Axillary temperature, 102⅘°; pulse, 160, after crying. The bowels are regular; the face pallid and anxious, the patient fretful when disturbed, and each day attacks of vomiting occur, and the vomited matter presents the ordinary appearance. Dr. Smith examined the patient thoroughly. The action of the heart though rapid was accompanied by no perceptible abnormal sounds, and the urine, tested by heat and nitric acid, was found free from albumen. From the history and appearance of the child, especially from its pallor, anxious features, and the persistent hacking cough which closely followed the cough of pertussis, Dr. Smith believed that the case was one of acute miliary tuberculosis, though the possibility of its being typhoid fever was considered. Three grains of quinine were given every six hours. Between 5 and 7 P.M. she had a copious evacuation from the bowels of very black blood, which strengthened the suspicion that the disease might be typhoid fever.

August 27th.—10 A.M.: Temperature, axillary, 102°; pulse, 160; has vomited often since yesterday, but no blood. An enema of hot water was given last night, since which no bloody stool has occurred. 2 P.M.: Tem-

perature, axillary, 104⅘°; pulse, 168; heart carefully auscultated, but no abnormal sounds noticed; its action, while very frequent, was strong and irritable. 8 P.M.: Temperature, 102⅗°; pulse, 144; had one normal stool since last record; has vomited much, for which bismuth and pepsine have been administered.

August 28th.—Had one dark stool since yesterday, not bloody.

August 30th.—10 A.M.: Temperature, 104°; pulse, 150; slept at intervals during the night; breathing still labored, and sighing; she takes nourishment readily and in fair quantity; physical examination of chest reveals only the abnormal breathing. 8 P.M.: Temperature, 102⅘°; pulse, 140. About two o'clock this afternoon she had a passage from bowels, consisting of about three tablespoonfuls of red blood, and another of the same character, but not so copious, a little later. For these she was ordered an enema of hot water and alum.

August 31st.—10 A.M.: Patient rested pretty well last night; temperature, 104⅗°; pulse, 160. 3.20 P.M.: Temperature, 102⅘°; pulse, 150. 7 A.M.: Temperature, 103⅛°; pulse, 150; respiration, 36; tongue coated and dry; some tenderness on pressure over abdomen.

September 1st.—10 A.M.: Temperature, 102°; pulse, 144; general condition about the same. 8 P.M.: Temperature, 103°; pulse, 140.

September 2d.—8 A.M.: Temperature, 101⅘°. 3 P.M.: Temperature, 103°; pulse, 140; a good deal of vomiting to-day; hands and feet cold.

September 3d.—7 A.M.: Temperature, 98½°; frequent vomiting. 11 A.M.: Temperature, 105½°; pulse, 168; head hot, hands and feet cold. 8 P.M.: Constant vomiting. To-day for the first time small extravasations of blood were observed under the skin, especially over the abdomen, and a few fine râles were observed in the right side of the chest, probably produced by extravasated blood in the alveoli of right lung; temperature, 102⅘°; pulse, 150; respiration, 44.

September 4th.—8 A.M.: Patient vomited blood twice this morning; temperature, 101⅘°. 2 P.M.: Temperature, 100½°.

September 5th.—9 A.M.: Temperature, 102°.

September 6th.—Died at 7 A.M.

This patient was examined by several physicians, but to all of us the disease was obscure. Acute miliary tuberculosis, typhoid fever, and purpura hemorrhagica were considered, but no positive diagnosis was made.

Autopsy, September 6th, nine hours after death.—Numerous points of extravasated blood underneath the integument; general paleness of all the internal organs. Brain: Entire right anterior lobe, except that looking toward the median line, covered by extravasated blood, which filled the intergyral spaces; a similar extravasation, but less in extent, over the right posterior lobe; no points of extravasated blood noticed in substance of the brain; small extravasations of blood under the pleura, and in substance of lungs, no other pulmonary lesions; similar extravasations underneath the peritoneum, and in substance of liver and spleen; none observed in the kidneys, which may explain the fact that the urine remained free from blood. The entire gastric, and a considerable part of the intestinal mucous surface, presented as mottled an appearance as the skin in measles, due to the extravasation of blood in and underneath it.

The state of the heart was of chief interest. In this organ we found the primary disease, to which all the symptoms were referrible. A small quantity of blood was found in the cavities, but an oblong fibrinous concretion was attached to the mitral valvé; its length three-fourths of an inch, its breadth one-third of an inch. The curator, Dr. Northrup, will state the results of his examinations, which establish the diagnosis of an ulcerative endocarditis.

This child, so far as known, never had rheumatism. It is only of late years that ulcerative endocarditis has begun to attract attention, and a number of cases have been reported. During the present year a case occurred in the Middlesex Hospital, London, and in the discussion it was proposed to designate the disease septic endocarditis. What may be the relation of micro-organisms to it, I am not prepared to say, but I believe that micrococci have, as a rule, been found in abundance upon and under the surface of the endocardium in those who have perished from this disease. The contamination of the blood and the infarctions seem to result entirely from the endocarditis.

Report on the pathological specimen by Dr. W. P. Northrup.—Heart and liver: From the margin of one cusp of the mitral valve hangs a pyriform body about two centimetres in length, half as wide at its widest part, its pedicle having a diameter of about a half centimetre. On the contiguous portion of the opposite cusp is a nodule of about the same diameter as the pedicle of the first. Its surface has a rough, villous appearance. Another nodule, much smaller, of similar appearance, is situated on one of the columnæ corneæ, at the level of the dependent end of the adjacent polypoid body. About six other small, some minute, points of similar appearance are found in the same (the left) ventricle.

Microscopic examination of the polypoid body shows nearly all of it to be made up of fine granular matter, composed largely of rod-shaped bacteria, coated on the surface with recent fibrin and white and red blood-cells. The peduncle fits upon a cone of new growth from the valve. The section now under the microscope is a longitudinal cut through the polypoid body, extending also through the cone-shaped base into the substance of the valve. In this section the whole process is manifest.

From below upward we find four gradations. (1.) Granular matter of polypus, made up of rod-shaped bacteria mostly. (2.) At the margin of the wart-like excrescence a zone of necrosis showing pus, broken-down tissue, etc. (3.) A broader area of swollen cells, either of connective-tissue cells or new cells, some pus, swollen and granular fibres. (4.) The deeper tissue of the valve in nearly normal condition.

The second section is a similar view of the nodule on the contiguous portion of the companion cusp. The process here shown is the same, though less advanced. It shows swollen cells, zone of necrosis, adherent granular mass skirted by fresh blood-clot. In both cuts the white cells in the clot increased markedly in proportion to the red, especially next to the granular matter, and are deposited in strata. The heart muscle and the liver were examined. The liver is the seat of moderate fatty infiltration. Neither liver nor heart muscle show micrococci.

This case seems to me, taking the history and the lesions, to furnish a typical section of malignant endocarditis or acute ulcerative endocarditis. There are no ulcers showing loss of substance. The lesion in this case is the nodular outgrowth of connective tissue, forming vegetations on the margin of the valve, the outer margin becoming ulcerated; upon this roughened surface the fibrin accumulated and formed the polypoid body. The part played by the rod-shaped bacteria I know nothing of. They are there in myriads.

The Society then went into executive session.

Prophylaxis of Migraine.—Dr. Haig reports in *The Practitioner* the case of a young man, thirty years of age, who suffered torments from frequent attacks of hemicrania, which ceased entirely after he adopted a purely vegetable diet, although they had recurred as frequently as three times a week before that time. Dr. Haig thought that possibly the neuralgia was caused by poisoning with ptomaines formed in the intestinal canal during the digestion of meat. After living upon an exclusively vegetable diet for a considerable time he was able gradually to return to a bill of fare containing a small quantity of meat.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 6, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE PATHOLOGY OF SENSORY APHASIA—WITH A SPECIMEN.

DR. R. W. AMIDON read a paper based upon original observations in one case, with a review of the history of twenty-three others reported by different authors.

The specimen was accompanied by the following history: A female patient, sixty-four years of age, married, had been in perfect health up to nine years ago, when she began to suffer from flatulent dyspepsia, headache, and other neurasthenic phenomena. Six weeks before Dr. Amidon first saw her she was seized with severe pain on the left side of the head, which continued three days, when she became flighty and excitable, and vomited.

At the date of his first visit, June, 1883, the right pupil was larger than the left, the tongue deviated slightly to the right, the right hand was not as much stronger than the left as it should have been, and it was somewhat tremulous. There was no weakness of the right lower extremity, and no marked disturbance of motility. The fundus oculi was normal, and acuity of vision was apparently perfect. With regard to speech, it was only in answering questions that she spoke incorrectly. She gave inappropriate answers to interrogatories, she could not count, or say letters, but when she spoke of her own accord her remarks were connected and intelligible. She knew all her friends except her husband, but called her son her father. She could not read and could not be induced to write. She could hear well, and could sing correctly. She was subject to periodic attacks of a spasmodic nature, occurring at intervals of about a month, characterized by a cry, a drawing up of the right hand, and drawing of the mouth to the right, followed by general convulsions, sometimes with involuntary evacuations. February 15, 1884, she was seized with a convulsion at 7 P.M. which continued until 11 A.M the 16th, when she became comatose and in this condition died. Her family stated that during the last twenty-four hours of life she passed very little urine.

At the autopsy the kidneys were found to be the seat of advanced interstitial changes.

The right cerebral hemisphere was normal. On the left side there was an irregular depression, with destruction of the cortex by softening, involving the inferior parietal lobule, the angular gyrus, the second occipital and the first temporal convolutions. There were atheromatous changes in the vessels supplying these parts, one of them being entirely occluded.

Dr. Amidon then presented eight diagrams and read the histories of cases reported by Balzer, d'Heilly, and Chautemesse, A. B. Ball, Chauffard, Giraudeau, Seppilli, and others.

Of the twenty-four cases, in eight with lesions affecting the visual and the auditory regions of the left hemisphere there was both word-blindness and deafness; in two in which the area of vision alone was affected there was word-blindness; in fourteen with the lesion in the auditory region there was word-deafness.

Dr. Amidon drew the following conclusions: Word-blindness is an incapacity to understand speech, written or printed, vision and intelligence being preserved. It is generally dependent upon a destructive lesion of parts of the inferior parietal, middle, angular gyrus, and second occipital convolutions of the left side. Its mechanism consists of an abolition of the transformation of written words into visual verbal images.

Seppilli's conclusions were that word-deafness was a lesion of speech clinically and anatomically distinct from aphasia. It was often associated with amnesic or motor aphasia, or with word-blindness. The lesion of word-deafness consisted in destruction of the first and second left temporal convolutions. Its mechanism consisted in abolition of transformation of spoken words into verbal images. He considered word-deafness of great value in locating a lesion of the left temporal lobe.

DR. FRANK H. HAMILTON then read a paper entitled

THE ASIATIC CHOLERA AT SUSPENSION BRIDGE, 1854, AND ITS LESSONS—WHAT WE KNOW OF CHOLERA.

The paper was the fulfilment of a promise made to the editor of the *Buffalo Medical Journal* in 1854, to write a paper, some time, on the Asiatic cholera as it prevailed at Suspension Bridge that year. After directing attention to the extreme fatality of the epidemic and its rapid spread among the workmen at Suspension Bridge, the author ascribed the great mortality to the elevated temperature, moisture of the ground, and alluvial, recently upturned soil. It was at the request of Dr. Rogers that Dr. Hamilton and two other physicians visited the patients during this epidemic. The following lessons which he had drawn from it were not presented as new, but as being entitled to special notice in view of the fact that we were liable to have cholera imported into this city at any time. His opinions would be expressed chiefly upon the question of what is the present state of knowledge of the nature, the etiology, the mode of propagation, and the treatment of Asiatic cholera.

First, Dr. Hamilton claimed that we had no positive knowledge of the existence of a specific cholera germ. In 1854 an Italian physician described a germ to the presence of which he ascribed the development of cholera. Recently Koch had discovered the comma-bacillus, which he regarded as the true cholera germ, but after reviewing the facts for and against Koch's views, and the observations of others who had investigated the subject, the author stated that in view of the conflicting testimony with regard to the theory of Koch that the comma-bacillus was the cause of cholera, we were justified in the assertion that the claim had not been established.

Even if it were determined that the comma-bacillus was always present in cholera and never in other disease or in health, it would not be certain that the bacillus and cholera stood in the relation of cause and effect.

Again, the theory was also defective in that it had not been shown that the introduction of this germ into the animal system would produce cholera. The inoculations by Koch himself, practised upon the lower animals, had been barren of results.

Again, if it were established that a microbe was the cause of cholera, the question would remain to be answered, which of the microbes hitherto described, or yet to be discovered, would prove the efficient agent. But it might still remain to be proven, should the experimentalists succeed in producing cholera by the introduction of a fluid containing a germ or germs into the system, whether the efficient agent were the fluid or the germ. It might be the fluid containing the microbe which was the cause of cholera, this fluid having taken on properties which no microscope could detect. The author did not wish to be understood as underestimating the importance of microscopical studies; much useful information had been derived from the microscope in the study of disease; but so far as the cholera or other epidemic infectious diseases were concerned microscopists had not taught us any important lessons either with regard to their cause or their prevention. Germicides kill the microbes when attacked outside of the body, outside of their native soil, but within the body these remedies had no effect upon them. Consequently, patients continued to die of cholera after the discovery of microbes. Again, it had not been positively proven that the active agent in the production of the disease resided in the intestines; the symptoms would indicate that it might also exist in the blood.

The cholera germ, using this term in its general signification, might be conveyed from place to place by the

clothing or any other textile fabric, by articles of food or water, or animate or inanimate substance. It might be conveyed a considerable distance by the air—how far it would be difficult to say; probably much would depend upon the force of the wind and other atmospheric conditions. He had reason to think it could not be thus conveyed farther than a mile or two. The theory of Koch, that the germ only found its way into the system through the mouth and stomach, was corollary to his theory of causation by the comma-bacillus, and that introduction of the poison through the mouth and into the stomach might be one of the means of propagation could be admitted, but that it was the only means the history of epidemics showed not to be true.

It was not necessary to assume that because the intestinal secretions were changed, or the mucous membrane congested, that the virus was originally implanted in the intestinal canal. The blood and the renal secretion also underwent changes quite as marked as those which took place in the intestinal secretions.

Although the cholera virus were received into the human system it need not necessarily give rise to cholera. It seemed probable that every person living in a cholera atmosphere received more or less of the virus into the system, but only a small proportion of these persons took sick and died. It was true of all the infectious diseases that the reception of the virus into the system did not necessarily produce that specific disease. It was also true, however, that a large proportion of those exposed to infectious diseases became infected, whereas only a small proportion of those exposed to cholera took the disease. A suitable soil was necessary. Cholera also differed from other infectious maladies in that one attack did not insure protection against another.

The conditions which protected against cholera were all those which went to prevent disturbance of the alimentary canal; also the avoidance of impure air, overcrowding, bad ventilation, decaying vegetable or animal matter, stagnant water, a warm and moist condition of the atmosphere. The most efficient agent for the propagation of the disease seemed to be the vapors rising from newly exposed soil, and decaying animal and vegetable matter, together with a warm and moist atmosphere. That filth was not the only efficient cause of the spread of the disease was shown by the fact that, during the epidemic at Buffalo, those persons living in dirty shanties on a sandy soil by the lake escaped. But there were instances on record which went to show that a favorable condition of the soil and atmosphere alone would not check the spread of the disease, if other local conditions sufficiently favored its spread.

The profession had long sought for a specific against Asiatic cholera, but there were really but very few specifics against any diseases, and none had yet been found for infectious diseases. But in the case of scarlet fever, etc., the disease would run a certain course, and we could only seek to conduct the case to a favorable issue, whereas in cholera, if we took it in time we could often abort it. It was seldom, however, that a patient was saved to whom remedies were not administered until after the period of collapse had arrived. The remedies which had proven most successful were those which had long been known to be most successful in the treatment of diarrhœa, cholera morbus, and analogous affections. The most efficient means prior to the stage of collapse were opium and rest. Dr. Hamilton preferred opium in the solid form to morphine. The patient would be more likely to recover were he removed to a region not favoring the propagation of cholera, and usually it would be found that the disease would not be spread in his new domicile.

It was believed that the cholera was brought to Suspension Bridge by some immigrants, but these people did not, so far as was known, suffer from the disease either before their appearance at Suspension Bridge or after their departure, which went to prove that the rapid spread and fatality of the affection among the laborers there was due to the condition of the soil and atmosphere. Again, in only a few instances, and in which the topographical conditions were favorable, was the cholera virus carried to and spread in neighboring localities.

Should cholera appear in this city, would it prove as fatal as it had done in Naples and the South of France? Dr. Hamilton answered in the negative, and for the reason that our climate is more favorable, our system of sewerage better, and we had efficient sanitary measures for the prevention of the spread of the disease. He referred to the success attending the efforts of the Sanitary Commission in stamping out cholera from Blackwell's Island in 1866, and spoke of the efficient work done by Dr. Yale, then one of the house-staff.

Dr. L. M. Yale said that his own experience with cholera had been confined to the epidemic on Blackwell's Island referred to by the author of the paper. The report which he then made included also the experience of his associates upon the Island.

The epidemic broke out at the workhouse. It had been preceded by a period of great heat and also the prevalence of diarrhœal troubles throughout the Island. It became necessary, therefore, to put diarrhœal remedies in various parts of the buildings, so that the patients could get them without the trouble always of searching for a physician.

The water-supply for a time was cut off, owing to some defect in the system of supply, and the bread had been sour for a short time.

The first case of Asiatic cholera occurred in the workhouse, although there had before been some cases of sporadic cholera in Charity Hospital. By the third day after the appearance of the first case Dr. Yale had thirty-three cases—twenty-three of which proved fatal—and about twenty per cent. of the entire number of inmates were carried off before the disease was checked. The epidemic occurred principally on the lowest ground of the island. More women contracted the disease than men, and this might be accounted for by the fact that the men went out to work by day, and their wards were larger; the women remained in the wards, and the evacuations stood in a tub in a room where the inmates often remained for a considerable time in conversation with one another.

Again, the patients, being unwilling to go to the cholera hospital, tried to conceal the fact when they were seized with diarrhœa. These faulty conditions having been corrected, the cholera was rapidly and permanently stamped out.

Dr. Yale mentioned one circumstance which was not easily explainable; namely, that in one pavilion as many as thirty cases of cholera developed; whereas in another pavilion, not thirty feet distant, not a single case occurred, although the conditions, so far as could be observed, were no better in the one than in the other.

Dr. Francis Delafield said he supposed all would admit that cholera belonged among the infectious diseases, or a class of diseases which did not develop unless the human body were infected by a specific poison. No matter how bad the influences under which human beings lived with regard to soil, food, and hygiene in general, they might develop many other diseases, but they would not develop cholera unless there were added to these other favoring conditions the specific poison that belonged to the disease. Whether that specific poison had always to be imported into new regions to develop the cholera, or whether it were capable of originating in new regions, might be a subject of dispute, but experience seemed to show that its home was India, and that other regions did not suffer until the poison was imported.

It being admitted that the disease was due to a specific poison, the question came up, What is that poison? Here we have had all varieties of theories, none of which have proven particularly satisfactory. The latest theory,

to which attention had been called this evening, was that, in accordance with the prevalent doctrine of the times, most of the infectious diseases are due to the presence and growth of certain minute organisms. Fashions of this kind in science and in medicine sometimes prove good, and sometimes prove bad; and whether a given fashion will prove the one way or the other could be known only after the lapse of some period of time. Dr. Hamilton had stated very fairly the evidence for and against this view of the causation of cholera. He had not stated, however, what Dr. Delafield considered particularly important to be borne in mind, namely, that there were only a very few men whose testimony was of any value in speaking of the presence or absence of germs in disease, and the reason was the very great difficulty attending the manipulations incident to the proper performance of the experiments.

Dr. Hamilton had called attention to the very important point of the bearing which the condition of the soil and hygiene had upon the development of cholera, and this might be briefly expressed in this way: Whatever conditions of air, of temperature, of soil, of food, and of general hygiene would predispose to the development of diarrhœa would also predispose to the spread of cholera. In other words, wherever there was present a predisposition to diarrhœa and also the specific poison of cholera we would have cholera developed in its worst form and to the widest extent. If all these predisposing conditions are absent, then the cholera germ may find its way to the place and not produce cholera at all.

This seemed to bring us to the means by which we can prevent the spread of cholera. In the present state of civilized society, quarantine measures seemed to prove useless if commercial relations were to be continued with other countries. What we should do was to seek to remove all the conditions which favor the development of the disease.

Dr. A. L. Loomis said that his personal experience with cholera had been limited to a few cases which he saw in this city in 1866–67, and he had therefore felt, when requested to discuss the paper, that he was largely in the position of one who was simply a student of the literature of the subject.

It seemed that, at the present time, we might justly divide the infectious diseases into three classes, according to the nature of their specific causes.

The specific cause in the one class produced its disease on being transmitted to the well person directly from one already infected. There was no evidence that the exanthematous diseases were transmitted in any other way than by direct or indirect exposure to the contagion.

The second class was that in which the disease was due to exposure to a poison developed outside of the human body, as decomposing organic matter.

The third class was that in which the poison developed within the living organism, or one affected with the disease, and was capable of reproducing the disease only when it had undergone certain changes after its discharge or removal from the infected person. To this class belonged typhoid fever, and cholera, as Dr. Loomis believed from his study of the literature of the subject. The home of cholera seemed to be Bengal, and epidemics in other parts of the world could always be traced as having originated there. He did not believe that cholera was ever of spontaneous origin. Dr. Loomis then gave instances which went to show that in every epidemic of the disease its origin could be traced to spread of the contagion through soiled clothing, infected water, etc. The view that the poison was active only after it had undergone certain changes on being removed from the human organism was favored by the fact that those making autopsies, those attending the patients, and microscopical observers of the fresh discharges, seldom contracted the disease. He was of the opinion that the poison entered the body only through the mucous membrane, but not necessarily by way of the mouth and stomach.

Sufficiently strict quarantine relations would prevent the spread of cholera, but the difficulty of establishing such quarantine had already been mentioned. The efficacy of the treatment spoken of by the author of the paper had been of great interest to him.

Dr. John C. Peters showed maps illustrating the spread of cholera from its home in India, and speaking of preventing an epidemic in this country by quarantine, said that so long as Denmark enforced her quarantine relations she had escaped from cholera, whereas as soon as those restrictions on one occasion had been removed the disease poison was imported, and she, with many other cities of neighboring countries, had many inhabitants perish. Quarantine had also proven efficacious in Greece.

The Academy then adjourned.

Correspondence.

THE INDUCTION COIL AND ITS VARIETIES —A CORRECTION.

To the Editor of The Medical Record.

Sir: In my article on the Induction Coil, etc., in the last issue of The Record, I wrote, that if the subject is "presented with any measure of clearness, it ought to be of some little service to those who are interested in, but have given little thought to, the matter." If, however, any one, even though he be the veriest expert in physics, can make head or tail to Fig. 2 of said article, he must possess a keenness of insight quite phenomenal. The continuous coil-induction apparatus is used by many physicians throughout the country, but its physical, physiological, and therapeutical characteristics seem to be little understood; and, therefore, in this paper I endeavored to answer as concisely and clearly as possible the many questions that have been put to me, both personally and by letter. Unfortunately, however, through some oversight, neither the printed matter nor the cuts were sent to me for revision, and the result is, an unintelligible description. A correct understanding of the part devoted to therapeutical considerations hinges upon this cut. As soon, therefore, as a new one can be made, and for the benefit of not a few of your readers who are interested in this matter, I trust you can find room for its reinsertion.

A. D. Rockwell, M.D.

OUR LONDON LETTER.

(From our Special Correspondent.)

SIR JOSEPH LISTER ON CORROSIVE SUBLIMATE AS AN ANTISEPTIC DRESSING—THE HARVEIAN ORATION—ANOTHER DEATH FROM THE SUCKING OF TRACHEOTOMY TUBES IN CASES OF DIPHTHERIA.

London, October 25, 1884.

The event of the week has been the delivery of Sir Joseph Lister's address on Corrosive Sublimate as a Surgical Dressing. This event took place last Monday at the first meeting for this session of the Medical Society of London. Sir Joseph commenced his address by frankly acknowledging that he had had during the past twelve months instances of failure with antiseptic dressings and one fatal case. This induced him to turn his mind seriously to the subject, and he came to the conclusion that the volatility of many antiseptics is a cause of their inefficiency. They are completely preventive of sepsis when first applied, but this protective influence gradually lessens. Eucalyptus gauze was very troublesome to manufacture properly, and required great care both in the original preparation of it and also to preserve it unimpaired afterward. Sir Joseph mentioned incidentally that, as regards the carbolic dressings, he had found a week

the limit of time during which a carbolic acid gauze dressing might be regarded as effectual.

Salicylic acid was non-volatile; iodoform only very slowly volatilized. Neither of these had he found to be powerfully germicide. His attention had therefore been directed to corrosive sublimate. With regard to this agent numerous experiments were narrated at length, as well as cases in which it had been successfully applied. Koch's experiments with this substance were referred to. Koch had found a solution of only one part of corrosive sublimate in twenty thousand parts of water quite sufficient to absolutely destroy the vitality of the spores of the bacillus anthracis. One part of sublimate to three hundred thousand of a solution of extract of meat had been found by Koch sufficient to "inhibit" the action of the spores, *so long as they remained in it.* The "inhibitory action," as Lister terms it, was, he said, sufficient in surgery.

The "wood-wool sublimate" used in Germany was, he remarked, inconveniently bulky, so he had had a gauze prepared containing one per cent. of sublimate. This he had found sufficient, but he had found the protective (dipped in a solution of one in five hundred) irritate the skin. Numerous experiments were fully described in his long address, but the result at which Lister has arrived is the use of a gauze prepared with a solution of one part of sublimate in one hundred parts of blood serum from a horse. The original precipitate caused by the addition of albumen to a solution of corrosive sublimate is, he finds, soluble in excess of the albuminous serum, and the resulting solution is efficiently antiseptic. Two and a half parts of this solution are contained in each part of the gauze. Gauze thus prepared has not caused irritation. That prepared from a solution of one part of sublimate to fifty of serum has in some instances done so, but this has disappeared when the weaker gauze has been substituted. Lister strongly recommends that during the first twenty-four hours after an operation this gauze should be used in abundance in at least sixteen layers. With the sero-sublimate gauze dressing the "protective" is not used, and the outer wrapping of mackintosh is unnecessary. The instruments used during the operation cannot of course be previously soaked in the solution as with carbolic acid.

The annual oration at the College of Physicians has this year been delivered by Dr. Russell Reynolds. This oration has lately attracted more attention on account of the counter-claim set up in Italy for Cisalpino as a discoverer of the circulation of the blood. This claim was pretty well overthrown by Dr. George Johnson in his Harveian oration of last year, and he has since written a pamphlet on the subject, still more conclusively establishing Harvey's claim to priority. The present oration was chiefly interesting from the prominent relief into which what may be called "foresight" on the part of Harvey was thrown by the lecturer. He showed that Harvey had some knowledge of reflex action, even as now understood. He also appeared to have some forecast of our present-day knowledge of the vaso-motor system, and had some idea of the action of sexual selection on the perpetuation of species.

Another instance of a medical man acquiring diphtheria with fatal results from sucking a tracheotomy tube on a diphtheritic patient is reported this week. Dr. Samuel Rabbeth was the senior resident medical officer at the Royal Free Hospital, and only graduated at the University of London in November last, when he obtained the scholarship and first gold medal in obstetric medicine. His death adds yet another to the list of brilliant careers cut short prematurely. Nearly all the newspapers are eulogizing his memory and holding him up as a hero to be imitated. A hero no doubt he was, for it requires more courage to incur such a risk than to rush to meet death in scenes of excitement. The question, however, occurs whether he ought to be imitated. Can it—on any theory of ethics—be the *duty* of a medical man to lay down his life, or even to incur the grave risk of catching diphtheria, for the sake of affording a moribund patient the distant chance of recovery? Dr. Rabbeth's case illustrates the melancholy fact that not only may a valuable life be lost, but, as in this case, be risked in vain; for his patient died after all. Surely a suction-apparatus might be tried by the operator before applying his mouth to the wound, and, in hospitals, there is no excuse for such not being at hand.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANGINA PECTORIS AND ITS TREATMENT—CHOLERA—HEALTH OF PARIS—HOSPITALS FOR CONTAGIOUS DISEASES.

PARIS, October 24, 1884.

THERE has always been great confusion, or rather misapprehension, as to the real nature or pathology of that terrible affection termed "angina pectoris," some looking upon it as a simple neurosis without any actual disease of the heart. Jenner, in 1799, considered that the disease in question was caused by ossification of the coronary arteries, whence the division into symptomatic and idiopathic anginæ. Other pathologists attributed the disease to atheroma, aortitis, affections of the heart, aneurism of the aorta. More recently Professors Germain Sée and Potain make out that angina pectoris is produced by the constriction or obliteration of the coronary arteries which result in cardiac ischæmia. Still more recently, Drs. Lancereaux and Peter, the former looking upon the disease as neuralgic, while the latter considers it to be a cardiac neuritis. Dr. Huchard, Physician to the Hôpital Bichat, in a work recently published by him, gives his experience of the disease, and seems to favor the theory advanced by Professors Sée and Potain. Dr. Huchard, placing the subject in a clinical point of view, divides the affection into *true* and *false*, or into organic and functional anginæ pectoris. The former is a rare disease and consists in an organic alteration of the coronary arteries, producing ischæmia of the heart, and which, sooner or later, almost always proves fatal. The pseudo or functional angina is much more common, and is met with as a complication of other affections, such as hysteria, neurasthenia, neurosism, exophthalmia, arthritis, rheumatism, gout, dyspepsia, etc., which angina is considered perfectly curable.[1]

As regards the treatment of angina pectoris, Dr. Huchard has found nothing equal to the nitrite of amyl, which he says fulfils the two principal indications: the suppression of pain and the overcoming the syncope which attend the disease.

Dr. Huchard prefers the nitrite of amyl to anything else during a fit. It acts with extreme rapidity, in a few seconds, and may thus prevent imminent death. Its action is explained as follows: It increases the activity of the intra-myocardiac circulation in the cases in which the latter is seriously impeded by the spasm or obliteration of the coronary arteries. Moreover, it acts on the peripheric arteries by producing dilatation in them, and by thus diminishing the peripheric resistance it favors and augments the energy of the central organ of circulation. Dr. Huchard administers the nitrite by inhalation in doses of three to six drops, which is poured on a handkerchief and may be repeated two or three times in the twenty-four hours. It is considered advisable to begin with the minimum dose, that is, three drops, which may be gradually increased to ten, twelve, fifteen, and even to twenty drops at a time. Dr. Huchard considers the nitroglycerine and the nitrite of sodium as inferior to the nitrite of amyl in the treatment of this affection. As adjuvants or preventives the author attaches great importance to the employment of the iodides of potassium or sodium, the latter being the more preferable, as it is

[1] This form is also produced by the abuse of tobacco, and is explained by the direct influence of the poison on the heart and its blood-vessels, and also by its action on the nerves of the heart and of the stomach.

better tolerated by the patient. Such is the treatment of the true angina pectoris. In the pseudo forms, the same inhalations combined with hypodermic injections of morphia may be usefully employed during the paroxysms, and hydrotherapy to prevent recurrences of the latter. The treatment appropriate to the concomitant affections must, at the same time, be rigorously attended to.

If the present cholera epidemic in this country, which, however, is gradually dying out, has been disastrous in one way, it has proved beneficial in many others. It has roused the people to a sense of the necessity of thorough sanitation, which I mean to be used in its widest sense—personal, domiciliary, and public. Everywhere sanitation is the order of the day, and among other measures the Parisians are only now beginning to look to their potable water, and they now admit that the water they drink may be the vehicle of disease-germs, and particularly those of cholera and typhoid fever, a fact long well known to them, but which up till now they have repudiated, simply because it was not a French idea. The sages have since discovered that the water of the Seine is a great deal more contaminated than it was twenty years ago, even in making allowance for the increase of the population, and projects have been set on foot in and out of the Academy of Medicine for its thorough purification, and for the adoption of such measures as may be necessary to prevent its being rendered foul.

Apropos of cholera, Dr. Leroy de Méricourt read his report on the numerous papers that were forwarded to the Paris Academy of Medicine on the nature and treatment of cholera, and among them was the report of the commission formed by the Société de Médecine of Marseilles, which concluded that Koch's theory was only a hypothesis without any foundation, and that the comma-bacillus could not be looked upon as the specific agent of cholera.

Paris is in a remarkably healthy state at the present time. It is free from epidemics of any kind, and even typhoid fever, which is generally so prevalent in spring and autumn, has been raging with less severity than it has done for many years previously, the number of deaths during the last two weeks being fewer than that shown in any previous weekly report of this year.

The Council of Hygiene and of Salubrity of the Seine has proposed the creation in Paris of refuge-houses where, in case of the occurrence of croup or any other contagious malady among children, parents could remove them at once. They will there be properly cared for until they have completely recovered, and thus prevent further contagion among other members of the family.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 2 to November 8, 1884.

SPENCER, W. C., Major and Surgeon. Ordered to Fort Trumbull, Connecticut, for duty as Post Surgeon, relieving Assistant Surgeon William J. Wilson, U. S. A., who will report at Department Headquarters and await further orders. S. O. 227, Department of the East, November 5, 1884.

CORBISSIER, W. H., Captain and Assistant Surgeon. Ordered to Fort Grant, A. T., for duty as Post Surgeon. S. O. 102, Department of Arizona, October 30, 1884.

HOPKINS, WILLIAM E., First Lieutenant and Assistant Surgeon. Ordered to Fort Lowell, A. T., for duty as Post Surgeon. S. O. 102, Department of Arizona, October 30, 1884.

EGAN, PETER R., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Lowell, A. T., and ordered to Fort Bowie, A. T., for duty as Post Surgeon. S. O. 102, Department of Arizona, October 30, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending November 8, 1884.

CRAIG, THOMAS C., Passed Assistant Surgeon. To the Alliance for temporary duty. November 1, 1884.

SWAN, ROBERT, Passed Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and placed on sick leave. November 3, 1884.

WIEBER, F. W. F. Appointed Assistant Surgeon. November 3, 1884.

November 8, 1884.....	0	22	7	2	8	37	0	0

A FRESH-AIR SUPPLY FOR CITIES.—A writer in the *Journal de Médecine de Paris* advances the curious proposition of furnishing all large cities with an abundance of fresh country air just as they are now supplied with gas and water. He draws a vivid picture of the countless benefits that would follow from the general adoption of such a plan. The sick and the debilitated would regain health and strength, while the capacity of city dwellers for intellectual and physical labor would be greatly increased. The method proposed is simple enough. A large open field is to be chosen in the country and this is to be surrounded with a high wall and planted around with balsamic trees so as to filter the air from dust. Then by means of an immense fan the air is to be forced through a large conduit and distributed through smaller pipes to the chambers in the dwellings and other buildings in the city. In summer the air could be cooled and in winter warmed before entering the houses. The imaginative writer calculates that by means of a turbinated wheel three metres in diameter and a twelve-horse-power engine, 120,000 cubic metres of air could be delivered to the city every hour. Such an atmospheric *rus in urbe* would be very charming, and so doubtless would be the odor of this once pure air after it had traversed several miles of city soil in company with the sewers and the gas-pipes.

TEMPORARY PRESERVATION OF POST-MORTEM SPECIMENS.—In the second number of *The Asclepiad*, among the Opuscula Practica, Dr. Richardson describes a method of temporarily preserving specimens taken from the dead body. A wide-mouthed bottle, with a large stopper, which is made to fit evenly by the use of a little glycerin, is filled with a mixture of common coal-gas and one drachm of ammoniated chloroform. The stopper is then tied down. Any part which is desired to be preserved is placed in a fold of soft muslin and gently pressed so as to remove superfluous fluid. The next point is to introduce the part enveloped in the muslin into the bottle without displacing more of the gaseous contents than necessary. The ammoniated chloroform is supposed "to prevent the breaking up of the water of the tissues," and the carbon monoxide of the coal-gas preserves the color of the specimen.—*Lancet.*

SOME MORE EXPERIENCES WITH JEQUIRITY.

By CHARLES SOHNLIN, M.D.,

ST. PAUL, MINN.

NOT many new remedies produced such an excitement as the jequirity did, but like every newcomer it had, and has still, to struggle hard before it gets the recognition which it merits. The opinions of the authors are still now divided: some of them praise it as one of the greatest remedies, others condemn it altogether, and a third class of authors keep quiet, waiting for what will be the end of the fight. What we want is the publication of some more clinical observations, *sine studio et ira*, but with a more special description of the peculiarities of the cases.

Let us first look over a little the clinical experiences of some authors. After a few favorable reports a great deal of opposition was made by Deneffe, of Ghent. He says he never got a good result, but he saw in one case a simple vascular keratitis becoming a pannus crassus, and he had in one case a perforation of the cornea. He always maintained the inoculation of gonorrhœic virus, and does not think the jequirity has any advantages over it; on the contrary, he thinks the effect of the jequirity is transient, while the inoculation of the gonorrhœic virus produces a permanent cure.

But about the same time Dr. Peschel, of Turin, published first twenty-two and then about eighty full cures with jequirity, without any failures or any accidents. He had only to produce the inflammation several times, then the eye healed up completely. Twice he met a slight infiltration of the cornea which quickly healed.

In this country the jequirity was first tried by Dr. Gruening, of New York, who published two favorable cases in THE RECORD, February 10 and March 17, 1883. After this Dr. Peck published five first-class results, and twelve cases succeeding in a less degree. He never had a bad accident to the cornea, only some transient desquamation. Also Dr. Hotz, of Chicago, Dr. Standish, of Boston, myself, and others published some very good results with jequirity. Dr. Landesberg, of Philadelphia, treated 9 cases, but had in 5 cases no result, in 2 cases a bad inflammation of the cornea, and in 1 case a panophthalmitis.

Some bad results were also published in Spain. Dr. Osio lost three eyes by panophthalmitis, and had one case of perforation of the cornea and one case of a large leucoma. Dr. Chiralt, another Spanish oculist, had only favorable results.

The Russians like the jequirity: Dr. Adamyk, Dr. Schmidt (40 cases), Dr. Maklakow (10 cases), and others.

In Algiers Dr. Sédan had, under 16 cases, 3 full cures, 7 cases were improved, 6 remained unchanged, and in one case he had a bad affection of the cornea.

In Italy, besides Dr. Peschel, also Dr. Mazza, Dr. Ponti. Dr. Guaita, Dr. Manfredi, and others, had some first-class results. They could not cure all their patients, but a great many of them. Dr. Manfredi had some bad accidents, he lost three eyes, but, as he says himself, by the use of too strong infusions of jequirity.

On January 28, 1884, there was in the French Society of Ophthalmology a very instructive discussion about jequirity, which is especially interesting because there were given some more special indications for the use of this important drug. Coppez had only first-class results, never a failure, and never an accident. Menacho and Vallez unite in praising the jequirity. Nicati saw some good results only when the cornea was covered with pannus, and never in the beginning of the disease. Some men, like Galozowski and Dor, never saw a good result, but Nachet cured ten out of eleven cases. Armaignac had, in the same patient, on one eye a first-class result, on the other eye a failure. He produced with the massage just as intense an inflammation as with the jequirity. Panas likes the jequirity, but only in some inveterate cases with pannus. De Wecker thinks it has to be avoided in all the cases where there is the least tendency to purulent discharge. Gayet and Bordet had thirty-three failures with children. They treated with jequirity some children two years of age, who had had, in their opinion, for two weeks, granulated eyelids. When you read Bordet's paper, you do not wonder that he obtained no result, you only wonder that he always continued to treat other children, after having had some failures with them, and that from an experience limited to children he drew conclusions about the general use of jequirity.

Some important indications for the use of jequirity were given by Von Hippel. He found, as Sattler, that the condition of the conjunctiva is of great importance. When it was covered with scars, then he never obtained a typical inflammation; the cases with papillar hypertrophy were also unfavorable. Besides, the condition of the cornea is of interest. A cornea which is still in good condition is in greater danger from jequirity than a cornea covered with pannus, or even an ulcerated cornea.

In cases of fresh granulations with much hyperæmia of the conjunctiva, Von Hippel never saw a disappearance of the granulations. But when the conjunctiva was pale and to a large extent covered by some hard, yellowish, prominent granulations, then he had some first-class results; if there was at the same time pannus, the jequirity had a good effect upon it, but it disappeared only after two to four months. Some first-class results were obtained in cases of expired trachoma, with atrophy and shrinking of the conjunctiva and a thick pannus.

After all these many observations it seems a little strange that Professor Jacobson, of Koenigsberg, Prussia, last summer, scared by one case of panophthalmitis he produced with jequirity, wrote a furious article against De Wecker and the jequirity humbug, as he expresses himself. He admonishes the other physicians to be cautious, "as his case did not seem to be the only one of this kind." Also his assistant, Dr. Vossius, had no good results with jequirity. He used it over fifty times, but he cured neither the acute hyperæmic nor the pale dry granulations. He got a good result only at times in cases of old trachoma with scanty granulations and pannus; still, in these cases he likes better the sulphate of copper. Besides, he had many accidents; three times an acute dacryocystitis, one time gangrene of the eyelids, fever, delirium, a long-lasting affection of the ear, and periostitis of the nasal bones. Once the opacity of the cornea grew worse and glaucoma was contracted; again, he had a purulent keratitis and panophthalmitis. No other author had such bad luck as Dr. Vossius. Dr. Chauzeix, of Paris, had better success; he used the jequirity also in fifty cases, and with good result. On

the other side, Dr. Schenkl, of Vienna, had thirty failures with jequirity.

I, for myself, am very well satisfied with the jequirity after an experience of over fifty eyes treated with it. But I selected my cases carefully.

First.—I never used the jequirity in a child's eye; my youngest patient was a girl of fifteen years, with granulations and pannus of two years' standing. She went three times through the jequirity treatment and was improved a great deal, but not fully cured. When I dismissed her she had still a few granulations at the fornix and a slight pannus. The conjunctiva looked white, the cornea a little cloudy, without veins; but when I kept the eyelids open for a while, then the conjunctiva soon became red and covered with veins, and also on the cornea appeared a few red lines which disappeared, together with the injection of the conjunctiva, within a few hours.

Second.—I never tried the cure in a fresh case of granulations with hyperæmia.

Third.—I never proposed it in a case of dry, yellowish, sago-like granulations, where the only trouble of the patient is sometimes a burning sensation with some weakness of the sight. I treated only two eyes of this kind, by the special request of the patient, with jequirity, but the granulations looked, after the treatment, exactly as before. I added a few weeks of daily use of bluestone, and succeeded in relieving the complaints of the patient, but the granulations still exist.

Such eyes are in another danger from the integrity of the cornea. I never had a bad accident, but the only trouble I had was in a case of five-year-old granulations with intact cornea; the patient, a girl of twenty years, had only on one side a little pannus at the upper border of the cornea. I was badly surprised, at the fourth day of the treatment, when the inflammation was going down, to discover in the centre of both corneæ a gray infiltration, which lasted about two weeks and left some slight opacities.

Fourth.—I would never dare to treat with jequirity a granulated eyelid during one of the inflammations which occur so often in this disease. The accumulation of the two inflammations might be fatal to the cornea.

The most favorable cases for the jequirity treatment are those of three years' or more standing, where the granulations have passed the acme of their development. If the eyelid is equally thickened and the granulations are no more very prominent, but are imbedded in the substance of the eyelid, and look more like spots than like buttons, and if the upper half of the cornea is covered with a narrow reticulum of fresh veins, which appeared when the patient "had caught cold" and existed for a few weeks without any change, then you have the most favorable case for the jequirity treatment. Two weeks after the first instillation of jequirity the pannus and granulations are gone, the inside of the eyelid is smooth and equal and has quite a peculiar appearance, yellowish, pale, and gelatinous, as if transformed into a substance like one of the granulations. As soon as you see this appearance you can take the patient for cured. The thickening of the eyelids never goes away.

Less favorable are those cases where you find the eyelids not thickened, but hardened and crooked, excavated at the inside by curvature of the cartilage, and covered with scars and some scanty prominent granulations, and where the cornea is covered with a thin membrane, consisting of pretty well developed connective tissue and a wide-meshed network of old veins.

While I cured every case of the former kind with one jequirity inflammation, I had in my cases of this latter kind always to repeat it, and to add for so long a while treatment with atropia and yellow ointment that I did not know to which I owed the final result. In these cases the corneal trouble has by-and-by grown independent of the granulations; it is (if there do not exist any irritating eyelashes) maintained by the irregular form and the scars of the upper lid, and the chief remedy is the atropia Bluestone, which gives so good results in cases without corneal trouble, is quite useless in such cases; yellow ointment does good if combined with atropia. I did not see any harm done by the jequirity; even the whole process of the cure seemed to be shortened by it, but it is too hard to judge about that, as the duration of the trouble is also very different when treated alone with atropia and yellow ointment.

When the cornea has been affected for a long while in a more serious way the corneal trouble continues after the granulations are gone, sometimes in the most favorable cases. One patient of mine, whom I treated eighteen months ago with jequirity with a good result, calls about every six months at my office with a fresh pannus; it appears quite suddenly in a night and disappears, after instillation of atropia, within a few days. When he came to me he had granulations of ten years' standing, the eyelids were thickened and covered at the inside with granulations. The cornea was covered with pannus and several ulcers and spots. The eyes had been sore the last four months without interval, and he was nearly blind. The granulations disappeared within two days after a treatment of five applications of a two per cent. infusion. The ulcers of the cornea healed up within four weeks, and left only some slight spots and an irregular astigmatism. The lids remained thickened, their inside became smooth and took the appearance as above described. For the watering of the eye I split the tear-points and introduced the probes a few times, as I always do after the jequirity treatment. After treatment in this way he was enabled to do his work as a stonemason, and till to-day there has been no change in his eyes except the above-mentioned slight attacks.

Another trouble which outlasts sometimes the granulations are relapses of iritis. If anybody with granulated eyelids contracts an iritis with synechiæ in connection with his corneal trouble, then, of course, this is not cured by the jequirity; still the strong diminution of the intraocular pressure, which cannot be produced by any drug in such a degree as by the jequirity, may have a good influence upon it.

As for the danger from the jequirity, I am not afraid of that. If we take the great number of cases treated with jequirity till now, in comparison with the few eyes destroyed by it, then we cannot say that it is a dangerous thing. Besides, we must take in consideration that a good many of the accidents happened in the beginning, when we were not yet acquainted with the indications for the use of the new drug. Manfredi allows himself that he used too strong solutions, others may have had some unsuitable cases which they would now no more treat with jequirity. It is hard for me to judge about that, because I could not find out the details of all those cases; but, for instance, Jacobson's case was absolutely unsuitable for the jequirity treatment. His case was a middle-aged woman, with evidently expired granulations. She had the last attack of inflammation fifteen years ago. Jacobson used the jequirity with the intention to clear up an opacity of the cornea which existed since the childhood of the patient, and was nearly free of veins. The inside of the eyelids were covered with scars. Jacobson does not say that he saw any granulations; besides, she had a blepharophimosis and a partial symblepharon posterius. Indeed he diminished, eight days before the beginning of the cure, the phimosis by cutting the external corner, but it is nevertheless more than probable that in this case the cornea was exposed to quite an extraordinary pressure. I do not think that from Jacobson's case any other conclusion can be made but that the jequirity was used in a case unfitted for it.

The presumption that all the cases ending fatally, in which no too strong solutions were used, have been in a similar way unfitted for the jequirity treatment, like the one of Jacobson, is the only explanation I can give for their loss. If the jequirity would be a dangerous rem-

edy, as the gonorrhœic virus seems to be for the eye, then I think I should also have had an accident in my fifty cases. I used in no case less than three applications of a two per cent. infusion within nine hours, the first one at 9 A.M., the second one after noon, and the third one at 6 P.M. Often I added even a few more on the second day, when the eye was already inflamed.

But I allow that the necessity of selecting the cases properly is a great impediment to the general use of the jequirity by the physicians. This is shown by the experience of Professor Jacobson, who selected his unfitted case for a trial with the jequirity just because he mistook it for a very suitable one. I should be happy if my lines would help a little in this regard, and I am fully convinced that the jequirity, if confined to the proper cases, will by and by get proper recognition as a beneficial remedy.

THE TREATMENT OF DYSPEPSIA BY HOT WATER.

By THOMAS W. SHEARDOWN, M.D.,

WINONA, MINN.

In reference to the paper entitled "The Therapeutic Effects of the Internal Administration of Hot Water in the Treatment of Nervous Diseases," as read by Dr. Ranney at the meeting of the New York Academy of Medicine, October 16th, and published in THE RECORD of October 25th, my own personal experience may afford some items of interest.

Let me premise by stating that I have, until one year ago this last September, always enjoyed the most robust health, have been something of an athlete, having required medicinal treatment but once in my life, and that for pneumonia when twelve or fourteen years old, from which I fully recovered in due time. During the last week in August, 1883, I came near being prostrated from sunstroke; did not lose consciousness, however, but came within an ace of it. The week following I commenced having some trouble with my digestion, vomiting occasionally, this emesis soon becoming more and more frequent until I vomited a portion of every meal taken. Now, by vomiting I do not mean just simply spitting up a mouthful, or a small portion of food now and then, but a square old-fashioned vomit, ejecting a major portion of the contents of the stomach *each* time. This act of emesis was preceded by no pain or nausea whatsoever, absolutely none, nor have I ever experienced *any pain* or *nausea either before, during*, or *after* the act of vomiting, simply an uncomfortable feeling which would not subside until the food was ejected; then instantly all was serene and quiet until after the next meal. I could vomit easily, with no trouble at all, and at any hour of the day or night. The usual time for ejecting my food (for it became a habit) was from one-half to two and a half hours after eating. There seemed not to be so much trouble with my powers of digestion as with absorption and assimilation, for the act of chymification seemed to be performed all right. The stomach seemed to prepare the food, but there it would lie in a pulpy mass, the system refusing to take it up, except, of course, in very limited quantities. I was not always actually compelled to vomit after each meal, for I could, by exercising all of my will power, keep it and carry it over a meal, or even two meals, but there it would lie, and until I emptied my stomach I was always uncomfortable—mind, no pain, or nausea, or heartburn, or anything of the kind; simply an uncomfortable feeling that was instantly relieved by emptying the stomach.

This condition of affairs went on for about three months, viz., from the first week in September, 1883, until the day after Thanksgiving. During this time I had tried all, or nearly all, the modes of treatment and remedies recommended by our best authors. All of the pepsines, pancreatines, lactopeptines, saccharalid and otherwise, acids and alkalies, strychnia, nux vomica, and arsenic, etc., *ad infinitum*; in fact, all of the recognized forms of treatment—of course endeavoring to govern, regulate, and restrict my diet. From the pepsines, lactopeptines, and peptones, I derived positively not the slightest benefit nor from the acid treatment. From alkalies followed by arsenic I received some temporary benefit, but soon relapsed into the same old rut of constant and regular emesis. I was constipated, of course, and was obliged to resort constantly to laxatives, and used the common "seidlitz powder" more than anything else. Aside from this, my general health was pretty good. I had a ravenous appetite all the time, invariably arising from the table hungry; had no headache, no pulmonary or catarrhal difficulty; urine normal in color and quantity, but a little deficient in weight. Occasionally would see the black specks of indigestion before my eyes, and at five or six different times my eyes would lose the power of accommodation for a short time only. In trying to read or write, my words would all run together and be blurred, and I could not make my pen follow the line, and for a few minutes I could not exercise the power of speech with control; I could not say what I wanted to. I would try to say a certain word or phrase, ask or answer a certain question, and I would say something else entirely irrelevant. I would know and realize instantly when I used the wrong words, and would stop and try again, and after several times trying and using all my will power in concentration of my mind and thoughts I could get my words right. These nervous irregularities only occurred a few times and only for a few minutes, not over ten or fifteen, at a time; but they were accompanied by a little, not much, dizziness, a very weak and faint feeling pervading the whole system—an indescribable sick feeling not to be localized, but general. These nervous phenomena and sickness would pass away immediately after lying down flat on my back.

I think I have outlined the details of the trouble from which I suffered. Let me repeat one thing to make the point I am coming to more striking. From the first week in September until the day after Thanksgiving—about three months—I vomited every single day, never less than twice (unless I would force myself to retain my food), and frequently four and five times. I am safe in saying I vomited not less than three hundred and fifty times in that length of time. I had lost fifty pounds in weight, and was becoming very nervous, irritable, despondent, and disheartened. Was losing all energy and becoming very weak. How I got enough nourishment to sustain life at all is still a mystery to me. I had been carefully dieting myself, and regulating and restricting food both in quantity and kind, with no benefit whatever, and on Thanksgiving Day I made up my mind I would eat at least one more square meal, let come what would, so I ate a hearty, old-fashioned turkey dinner, with its accompaniment of mince pie, English pudding, etc., topping off with a plentiful supply of egg-nogg. As a natural consequence, I was very sick, more so than ever before. Just the day previous I had read Dr. Cutler's article, in the London *Lancet*, on the use of hot water in dyspepsia, and without much faith made up my mind to try it. The last thing at night on Thanksgiving was to empty my stomach again, and the first thing the next morning I had my maid bring a pint of hot water, boiling hot, to the bed before I got up. I took a clean rubber catheter and sucked the hot water through that, it being so hot I could not touch my lips to it at all, nor hold the vessel in my bare hands. I drank all of the water in less than twelve minutes. I laid in bed an hour and a half, and then got up and ate my breakfast of porterhouse, baked potatoes, bread and butter, and coffee, and I kept it down, and with no unpleasant feelings. At 10.30 A.M. I drank twenty ounces of hot water taken from the fire boiling, and taken through a tube as before, ate dinner at 12 o'clock and retained it. At 4.30 P.M. I drank twenty-four ounces of hot water, and at 6 o'clock ate my regular supper and retained it. I drank sixteen ounces

more half an hour before retiring. The next day I went through the same performance again, taking sixteen ounces each time, and likewise every day until Christmas Day. Not once did I miss taking my water in sixteen-ounce doses, nor did I vary five minutes from my regular time; nor did I during that time take one drop of liquid food, milk, tea, coffee, or cold water, or any hot water, except at the time specified.

After the first draught of hot water not one single time did I vomit, until Christmas Day, when I foolishly omitted my hot water, and partook of a Christmas dinner from which I was sick the remainder of the day and the day following; but recourse to hot water soon corrected it. Now, this shows the efficacy of the hot-water treatment. It stopped the vomiting at once—not slowly or gradually, but at once. From Christmas until the middle of last September, about nine months, I used the hot water, but not as regularly as I should have done. I would use it a couple of weeks at a time, and it would stop the vomiting at once, but after ceasing I would occasionally eject my food, but only after some indiscretion in diet. I removed from Tennessee (Knoxville, where I had lived the last year) to my old home in Minnesota, and since I have reached here, my native State, and where I have lived nearly my entire life, I have been able to discontinue the hot water entirely, and remain well, gaining strength every day and fast recovering my normal weight. This change of climate has, of course, helped to benefit me. Then one great auxiliary to the hot-water treatment I have found out is an *almost exclusively meat diet*, putting as little of a fermenting nature into the stomach as possible. It has been said of this hot-water treatment that it is very slow in its effects. In my own case it acted at once, from the very first draught.

The *modus operandi* of the hot water in my own case, I must confess, I do not fully understand. I had always considered my trouble reflex in character, and due to some irritation to the pneumo-gastric from overheat. For the past ten months I have used hot water in my practice in quite a number of cases of dyspepsia, indigestion, and allied gastric troubles, and with most excellent results every time when the treatment was persevered in for any length of time. Ordinarily, I think, the hot water acts more mechanically than otherwise, by moderately distending the walls of the stomach and washing them thoroughly, carrying down all débris, thus leaving the stomach perfectly sweet and clean for the reception of food. The presence of the water hot would tend to allay the inflamed mucous surfaces, and also tend to stimulate the secretion of the gastric juices, cold water having a diametrically opposite tendency in my humble estimation. The ingestion of cold water, and, in fact, any and all fluids, must be absolutely prohibited; *no coffee, no milk, no tea.*

After drinking the hot water in the prescribed quantities regularly for two or three days, there will be no sense of thirst between meals, as it were, the draught of hot water effectually satisfying all the demands of the system for liquids. The patient will begin to even relish the large dose, which at first thought seems so unpalatable. I used the hot water all in all for nearly a year, and never got tired of the taste. There is only one objection to its use, and that is the amount of time consumed and the bother and trouble in its preparation. After continued use, should it pall on the taste, flavor with a few dops of essence of peppermint or cinnamon, or a few drops of any of the dilute mineral acids make a pleasant change.

The rules laid down by Dr. Cutler, also by Dr. Ranney, must be rigidly enforced. I can fully endorse them. Without following closely these directions you cannot make a success of the "hot-water cure." Let me formulate them again. 1. Prohibit absolutely all other liquids. 2. Drink the water in as large quantities as will effectually satisfy all demands of thirst, as hot as can be borne, four times daily, an hour and a half before each meal and half an hour before retiring, the object being to have the stomach as nearly empty as possible when the water is taken, and to give it time to get out of the stomach before food is taken, thus avoiding dilution of the food. 3. Limit your patients to as near an exclusive meat (rare) diet as possible.

These three rules, if rigidly enforced and followed out, I fully believe, will effectually control that bugbear of American physicians—dyspepsia.

November 1, 1884.

DEAD TEETH IN THE JAWS.

By R. WOOD BROWN, D.D.S., M.D.,

LATE DENTIST TO THE OUT-DOOR SERVICE OF THE LONG ISLAND COLLEGE HOSPITAL.

UNDER the above title there have appeared in THE RECORD several articles the reading of which has prompted me to pen this paper. I shall notice the different points irrespective of the order in which they appear, limiting myself more particularly to the editorial of October 4, 1884.

The statement in the fore part of second section of the editorial of above date says: "It would not be strange if, in the course of events," "when all teeth without pulps, and hence in process of more or less decay, as well as those which the deposit of tartar, or other cause, had entirely divested of periosteal nourishment, would be promptly condemned as unfit to remain in the jaws." We take the liberty of disagreeing with the editor as regards the first part of this statement, and we think he is wrong in the latter part.

Teeth without pulps are not necessarily dead. Dr. J. Morgan Howe, MEDICAL RECORD, October 18, 1884, writes correctly that teeth "are not in an appreciable degree deprived of periosteal nourishment by the death of the pulp." When we have a periosteum destroyed we almost always find a pulpless tooth, but we do not consider a tooth or root dead unless the entire periosteum is absorbed; a tooth may be a living structure long after the pulp is dead or removed. If we should extract a tooth in a normal condition, crack it open, and try to remove the pulp from its bed with a pair of pliers, we will notice that there is some difficulty in so doing. Why? Because the pulp is attached to its parietes by odontoblasts, which are connected to the pulp by small bands, and to the dentine by fibrillæ which enter the dental tubes. It is thus shown why the dentine is so sensitive when attacked by caries, also the part it takes in the nourishment of the member. Now, take the same tooth and make a section of the root, and we will find, under the microscope, that the dentine is composed of tubes one-ten-thousandth of an inch in diameter; that the crusta petrosa, or cementum, is made up of lacunæ and canaliculi, but no Haversian canals; also that the periosteum is full of blood-vessels. We will also see that the tubes are connected to the lacunæ and canaliculi directly and by interglobular spaces, and that the latter are in connection with the periosteum.

Again, if we view a transverse section of dentine, we will notice that the tubes contain fibrillæ or a substance capable of carrying nourishment. In a dry section, the contents being contracted, this substance can be seen more easily. We have now a direct connection between the dentine and periosteum, and can understand why the pulp is not necessary to the vitality of the tooth, having, as it does, ability to draw nourishment from the periosteum, thereby maintaining its normal condition. It should be remembered that membrane covering the pulp is continued through the apical foramen and becomes the periosteum upon the roots. If there is a membrane lining the pulp chamber, we have not been able to find it. What part the pulp takes as regards tooth structure, after the tooth is formed, is, we think, not positively known, but our experience tells us that teeth are just as liable to de-

cay with pulps as without them. The damage from caries is done before the dentine is reached; the cause of caries is from without, not from within. If a tooth is perfect when erupted, it will last a lifetime unless injured by acids or abrasion. Pulps counteract decay so far as to throw out lime salts into the dental tubuli, which make a more perfect barrier to the encroachments of decay; this same process goes on after a nerve is capped. The dentine after this change is called osteo-dentine; why, we do know, as our microscopical investigations have not shown any characteristics of bone in the so-called osteo-dentine.

This action of the pulp in resisting decay is the only part it takes in nourishing the tooth, and even here there is not sufficient pabulum thrown out to resist the encroachment, much less to restore broken down structure. The only result from the barrier thrown out by the irritated pulp is a retardation of the progress of decay. The very fact that a large number of pulpless teeth and roots are retained in the mouth without periostitis, ulitis, or suppuration, is sufficient testimony that dental pulps are not at all necessary to the retention of teeth; also that pulpless teeth should not "be condemned as unfit to remain in the jaws," and that teeth are not necessarily in the process of more or less decay" because deprived of nourishment on account of dead or extirpated pulps.

As to the latter part of the editorial statement—"as well as those which the deposit of tartar, or other cause, had entirely divested of periosteal nourishment, would be promptly condemned as unfit to remain in the jaws." The main point here is the divestment of the periosteum. We do not think a root ought to be removed for the reason that there is no periosteum; it does not follow that the root is offensive and discharging purulent matter because divested of its membrane. There are two kinds of decay, hard and soft, the latter emitting a disagreeable odor, the former not doing so. Memory bears us out in saying that crowns of teeth are more apt to be the prey of soft decay than are the roots. The exceptions in these cases prove the rule. If a root is entirely divested of periosteum, the crown gone and no diseased tissue surrounding it, there should be some hesitation before condemning and removing from the jaws. Every root taken from either maxillæ weakens the arch and seriously threatens its usefulness. Again, the presence of tartar or salivary calculi does not always threaten the life or usefulness of a tooth, even if the entire periosteum under the deposit is destroyed. We have seen teeth covered with tartar to such an extent as to preclude the probability of any membrane remaining, yet for years after they have been doing good service.

There are certain conditions which should govern the extraction of teeth or roots, and they are pre-eminently pathological. Periostitis, where it is not traumatic, indicates one of two causes, or may both—a diseased pulp or periosteum. Here it is bad practice to extract, if of recent origin; if chronic and the roots crownless, we advise immediate removal. If there is a probability of the disease abating and there is enough structure to work upon, then extraction should be a *dernier ressort*. Affected teeth with crowns are more liable to produce inflammation and its train of disturbances than are roots alone, owing to continued irritation by mastication.

Periostitis does not always destroy the periosteum, but, if mild and chronic, may produce a condition known as exostosis. This many times is the cause of neuralgia from pressure upon the nerve. Many patients are dosed with all the neurotics known, without the thought of chronic inflammation of the dental organs; yet, on the other hand, many a dental arch is sacrificed without causing relief. Teeth in which the pulp remains after death very often causes discoloration from hematine which is absorbed into the dental tubuli.

The editorial remarks in the latter part of the second section, relative to the danger from putrescent teeth, are not too strong, but to the point, and certainly they do not merit discussion; in fact, they are irrefragable.

The object of this paper is an endeavor upon the part of the writer to correct what he thinks is an erroneous idea—the idea that teeth, because diseased, should be condemned as unfit for the jaws; also to show why they should be allowed to continue their usefulness. It should not be forgotten that roots preserve the contour of the dental arch, and are not always foreign bodies when the pulp is destroyed, even if both pulp and periosteum have ceased to perform their functions. We know that many constitutional disturbances are attributable to diseased dental organs, and, owing to professional inability, many teeth are lost. This naturally leads us to the third section of the editorial mentioned, which speaks of dental education. It is lamentably true that a large number of dentists are utterly incapable of treating severe, complicated cases of diseased teeth, but we must not enter the field of dental education, although it is a subject which has occupied our mind and pen, and is still occupying our thoughts.

Eleventh and Main Street, Kansas City, Mo.

BUCCAL BREATHING.

Its Causes, Serious Consequences, Prevention, and Cure.[1]

By GEORGE W. MAJOR, B.A., M.D.,

late clinical assistant in the hospital for diseases of the throat and chest, london, eng.; instructor in laryngology and diseases of the throat, m'gill university, montreal, can.; fellow of the american laryngological association; physician to the montreal general out-patient department.

The habit of breathing through the mouth, instead of through the nose, is so very prevalent, and its serious results so little appreciated, that I have been induced to make it the subject of a few remarks before this Association. The first breath of life is taken through the nostrils, and if this precedent should not prove sufficient to satisfy us of the natural mode of respiration, let us refer to Genesis, where we learn that at the creation of man "He breathed into his nostrils the breath of life." The instinct of the savage mother leads her to carefully close the lips of her sleeping infant, lest the cold air might prove injurious should it enter the lungs by the passage of the mouth.

The professional trainer insists upon the athlete breathing with closed mouth. The fireman entering a burning building carefully avoids speaking, or the parting of his lips. It is recorded that one may breathe mephitic air for a short time through the nose, if the lips are firmly sealed. The army surgeon requires the raw recruit to undergo, in his examination, physical fatigue with closed lips.

All these decisions have been arrived at as the result of observation, though no doubt to many of those who insist that under certain circumstances nasal respiration should be strictly observed, the true reason for this precaution may be quite obscure, or perhaps entirely unknown. Nine out of every ten persons will tell you that the nose is the organ of the sense of smell, quite oblivious of the more important function of respiration.

This question of oral respiration is one that has not even at this late day received at the hands of the profession the study and research it truly merits. If it is the result of mechanical obstruction of a permanent nature, it is not a habit but an unfortunate necessity; but, on the other hand, temporary nasal swellings often develop a habit which is unconsciously and innocently pursued with the most serious results to health and development. Any one of a number of conditions may singly give rise to oral respiration, but we generally find more than one present before man allows himself to be converted into a mouth-breather.

In the human economy the nose performs several im-

[1] Read before the Canada Medical Association, held at Montreal, August 6, 1884.

portant functions, the chief being that of a respirator. It purifies, moderates the temperature and moistens the air before it reaches the sensitive larynx and lungs. It purifies the air by arresting foreign and irritating particles in their passage through the cavities of the nose. It moderates the temperature of the air by rendering it as nearly that of the human body as possible. It moistens the air by virtue of the secreting power of its lining membrane and glands.

An example of its first influence may be had in the fact that in oral respiration dust will lodge in the pharynx and larynx that under otherwise normal conditions would scarcely, if at all, gain an entrance to these organs. Of the second, on going into the cold outer air of winter a single breath through the mouth will, by its impact, provoke cough and a sensation of coldness, which, if taken through the nostrils, would be so moderated that on reaching the lower border of the palate it would give to one's sensation no appreciable difference of temperature, and could be breathed with comfort and impunity. Of the third, if from any cause nasal respiration is impeded, say during the night, we rise with dry, harsh palate, tongue, and throat, the secretion of the buccal mucus being neither so constituted nor sufficient to moisten the air and keep the parts themselves in a healthy state.

The mouth was alone intended for the taking of food and speech; it is, therefore, not very remarkable that many and baneful results should follow in the wake of those who violate the natural laws by putting parts to uses for which nature never intended them.

Certain physical deformities result from this habit, aggravated in the same proportion as that in which this hurtful method is practised. Among these may be mentioned general debility; malnutrition, as shown in spare habit of body and undersize; deformed chest, with prominent sternum, sunken sides, retraction at the line of attachment of the diaphragm, and rounded shoulders. The upper lip is more or less shortened, the mouth open to a greater or less degree, the upper central incisors generally prominent, with irregular development of the symphysis of the upper jaw. The alæ of the nose are thin and flattened, and the muscles of the nose and its neighborhood wasted. These conditions are always more marked on the side of greatest obstruction. The face presents a pinched expression. We also find an expression of stupidity in aggravated cases, with loss of memory occasionally—these two latter possibly the result more of internasal pressure than of mouth-breathing directly.

Dupuytren many years ago associated pigeon-breast with large tonsils; but in point of fact any interference with nasal respiration, be the cause what it may, will, if of sufficient gravity, produce this deformity. In addition to the appearance laid down as indications of oral respiration, I have observed an abnormal acuteness in the development of the upper jaw, whereby the hard palate is of great vertical depth, with corresponding narrowing from side to side. The central incisors in this class of cases are not prominent, but usually show at the middle line near the margin of the gums a point of decay.

It is also worthy of passing comment to note the frequency with which we encounter decay of the upper teeth. According to my idea this is largely dependent upon mouth-breathing. I do not think the prevalent opinion, that the cause lies in the escape of corroding gases from the stomach, is altogether a correct one. An offensive breath, in my experience, arising from the stomach, is somewhat infrequent. The odor, if not of decayed teeth, is most probably that of decomposed nasal or pharyngeal secretions, the tendency to change being manifest in disordered constitutional conditions, especially if accompanied by any elevation of temperature. The injury to the upper teeth may be regarded as the result of dryness caused by the passage of air between and around them, facilitating decomposition of any food present, and favoring the formation of acids capable of reacting vigorously. The lower teeth are protected by the lip and tongue, and moistened by the saliva, and are therefore free from the evil influences exerted above.

The injury to digestion, as a direct result of impairment of the power of mastication, at once suggests itself. It is not during the day only that the subject of oral respiration suffers; at night the aggravation is intensified. The position of the body during sleep favoring, as it does, increased flow of blood to the head, the result is increased difficulty, as shown by the open mouth, snoring, and general restlessness, the latter the direct result of deficient oxygenation, assisted no doubt by the fact that during sleep the voluntary respiratory muscles used during the day are no longer available.

I trust I shall not be considered as taking an extreme view if I should state that after a careful inquiry I have found that in a large proportion of mouth-breathers involuntary micturition during the night is not unusual. This latter, of course, is attributable to carbonic-acid-gas poisoning—the sensitive air-passage refusing to take in the cold, dry, impure air, and as a result, there is deficient lung expansion and aëration. It is unnecessary here to enlarge upon the consequences of deficient oxygenation, they are patent to every one.

The principal causes that lead to mouth-breathing are the various deviations of the nasal septum; ecchondrosis and exostosis of the nasal fossæ; hypertrophy of the turbinated bones or of their soft tissues; dilatation of the various sinuses, whether of a permanent or temporary character; tumors of various kinds, known as polypi; œdema of the septum, particularly common at its posterior border; overgrowth of the erectile tissue of the posterior terminations of the lower turbinated bones; adenomata of the vault of the pharynx, being an hypertrophy of Luschka's tonsil; growths in the same region, the most common being fibroids and hypertrophy of the buccal tonsils.

As the habit of mouth-breathing is developed usually in early childhood, its prevention must largely depend upon the recognition by those in charge of the formation of an unnatural and hurtful method of respiration. In order to do this, mothers and nurses must first know that the nose is the proper channel by which air enters and leaves the lungs.

If the practice is merely the result of *habit*, induced by some temporary nasal or naso-pharyngeal obstruction, the simple closure of the mouth after clearing the nostrils will generally suffice; or if still more obstinately pursued, a bandage tied under the chin and over the head will serve to keep the jaws in contact. If there be, however, any mechanical impediment, as swelling, hypertrophy, or growths, they must be treated radically. The age of the child never should negative surgical procedure, as the conseqences resulting from neglect of early interference may be fraught with very serions after-injury. In early infancy I have more than once used the galvano-cautery with the most satisfactory results.

It is manifestly the duty of the profession to teach the public that the nose is the organ of respiration; that it is also the organ of smell they will themselves discover. It now remains to briefly refer to the treatment essential for the removal of the obstacle to free nasal respiration. The first cause referred to, and perhaps the most common, is deviation of the nasal septum. I may say that in practice it is almost the exception to see a straight one. Deviation of the septum may be single, double, or multiple, and this may take place in a vertical, horizontal, or diagonal line, or present so many irregularities as to occupy every possible direction.

In many cases, especially of vertical deviation, the angle at which the cartilaginous septum is bent is so acute that the nostril in which the convexity presents itself is often so perfectly close as to be utterly useless for any purpose of respiration: the prospective gain on the opposite side is neutralized either by an hypertrophy of

the lower or middle turbinated bone and soft tissue, or perhaps by a second deviation posteriorly, giving the septum a sigmoid shape. As regards the side to which the deviation exists most frequently, statistics of over seventy cases compiled by myself do not show any very special selection as to right or left, but to the left, if anything. No doubt exists in my mind that deviations are the result of mechanical violence—blows or falls on the nose. Females, though presenting deviation, do so, for obvious reasons, very much less frequently than males, and also show a much less exaggerated type. In prize-fighters, or those who have engaged much in boxing, the cartilaginous septum is bent into every possible shape, without very severely affecting nasal respiration or the external form of the nose. In these cases the cartilage is telescoped downward much on the principle of a mast, but without radically closing the side passages. It has seemed to me that a vertical deviation is more likely to date from an injury received in childhood than from one later in life, and an analysis of cases strengthens this belief.

In May last I saw a lady, Miss T——, aged thirty-seven, who had been confined to her bed for five months, suffering from the most excruciating form of headache, which had refused to yield to a variety of treatment. On examination nasal obstruction from swelling of the mucous lining was found, deviation of the septum posteriorly, and more or less true hypertrophy of the turbinated bones. Means, such as nasal inhalations and sprays, afforded some relief by reduction of the swelling of the membrane, and much more decided, if not absolute immunity from pain was had by successive applications of the galvano-cautery. This result was obtained purely as the result of diminished pressure. At first the patient was incapable of even standing alone, but in a few short weeks had gained strength, and is now perfectly restored to health.

A second instance, Miss M——, aged twenty-eight, who had for some months been the subject of hallucinations, and, at times, of violent mania, was referred to me for a pain felt on the right side of the head behind the ear, and covering a space of the area of the palm of one's hand. Nasal obstruction in the right nostril, the result of deviation, was noted, and when in the course of three weeks it was somewhat reduced the mental condition had wonderfully improved, and convalescence is now complete. The pain, which was described as a sense of pressure, improved *pari passu* with the reduction of the nasal stenosis—as in like proportion did the mental state. Each must draw his own inference from the report of this case.

Under the head of deviation, a rather interesting abnormal hyper-development of the vomer, giving rise to buccal breathing, might find place. Miss D——, aged twenty-two, was sent to me for treatment by my esteemed friend, Dr. Arthur A. Browne, of this city. Nasal breathing was impossible, and more or less deafness was also complained of. The anterior nares showed no cause. On exploring the vault with the index finger a very peculiar state of affairs was found to exist. It gave the impression to the touch of a partition running antero-posteriorly, dividing the naso-pharynx into two separate lateral chambers. This bony extension refused to be displaced, and seemed continuous with the vomer in front, being joined to the vault above, and to the posterior superior pharyngeal wall behind. On examination with the rhinoscopic mirror the above description was verified. It was covered with mucous membrane, which had undergone catarrhal swelling, obstructing the passage of air and pressing on the Eustachian orifice laterally. Under appropriate treatment the engorgement was relieved, and with it all the discomforts for which advice was originally sought. There is but one other case of the kind on record, that reported by Dr. John N. Mackenzie, of Baltimore.

The fourth and last case that I shall present to you is that of a prominent canon who applied more for relief from vocal disability than for any pain or nasal inconvenience. He was a confirmed mouth-breather, probably from childhood. There was an extreme vertical deviation of the cartilaginous septum to the left, entirely obstructing the nasal passage of that side, while the concavity on the right was occupied by a long myxomatous tumor. The soft palate clung listlessly to the pharynx, having long since forgotten its function. The removal of the growth, which was of considerable size, afforded some relief, and as hypertrophies were reduced by local medication and the galvano-cautery, satisfactory progress was made. Though no attempt has been made as yet to operate on the deviation directly, manipulation of it twice or thrice daily by the subject himself, shows considerable alteration of its outlines. Meantime the palate has gained some tonicity, and breathing is carried on by the nose almost entirely. Snoring at night also has ceased, and the voice, some months ago, was sufficiently recovered to fill a large church at a crowded service. These disabilities, however trifling they may appear to the casual observer, may be, as in this gentleman's case, sometimes a serious obstacle to preferment. The health also suffers from the exertion necessary to make one's self heard from the pulpit; the naso-pharyngeal cavities ceasing to be resonators, much greater pressure is necessary to produce voice.

These cases have been briefly referred to for the purpose of showing how various and serious may be the consequences of internasal pressure, and how speedily and easily measures aimed in the proper direction may give assurance of relief and cure.

For the relief of deflection or deviation of the nasal septum a variety of means have been from time to time suggested, but it is practically only in cases of the vertical form that operative interference is either urgently called for or likely to be of value. The method (Ingalls', of Chicago) that most commends itself, both from its simplicity, as also its successful results, is that in which the mucous membrane of the deviated side and the cartilage are carefully divided in a triangular manner, the apex being upward, the cartilage dissected from the mucous membrane of the opposite side and removed, the septum being brought into line with pliers, and the divided mucous membrane held by sutures and a pad of some soft antiseptic material. The resiliency of the cartilage is such that a portion must be removed equal to the redundancy, in order to acquire a straight line. Of the many punches introduced but one seems to me to fulfil all the requirements, and at the same time to be comparatively free from fault. It is one (Sajous', of Philadelphia) in which a blade can be fixed at any desired angle, and the septum divided through from side to side, and straightened by allowing overlapping, or the excess may be removed and the cut edges placed in line and held by plugs until healed.

All the operations whereby openings between the nostrils were caused are unwarrantable, as forming a space for the accumulation of dried secretions. It is not unusual to find nature performing the operation of removal of the deviation by setting up ulceration and necrosis of a portion of cartilage of the size of a sixpence, or even larger. When this occurs pressure only is relieved, and no appreciable gain is secured the nose as an air-passage.

Ecchondrosis and exostosis are of not uncommon occurrence, and are capable of removal by scalpel, saw, or pliers, but more nicely by means of the surgical engine and burr; no violence is used, pain is trifling, and the time occupied in performance is very brief.

Hypertrophy of the turbinated bones, if very considerable, is also best reduced by the drill attachment, afterward crushing down and washing out the debris. The hemorrhage is slight compared with that resulting from the use of gouges and other means of destruction. Hypertrophy of the soft tissues, with or without dilatation of the venous sinuses, whether partial, general, temporary, or permanent, has for many years been looked upon

therapeutically as a most unsatisfactory complaint. When chronic, it has generally been termed hypertrophic catarrh, and when acute, hay-fever, summer catarrh, coryza, and so forth. The various methods adopted for the treatment of either the chronic or acute variety have been eminently unsatisfactory, more especially was this the case in the latter.

In the chronic variety caustics were employed, whereby large areas of tissue were destroyed, and great and prolonged pain ensued, or the actual cautery was introduced through the nostrils and applied so as to form deep sloughs, depending upon the cicatricial contractions for a cure. In the acute form the use of various lotions and pigments served the purpose of cleansing the tissue, with little or no effect in shortening the duration or preventing a recurrence of the attack.

Independently of the pain and risks attending the employment of caustics in the nose, the function of the organ must be somewhat interfered with if much of its lining membrane is destroyed, and on the latter ground alone recourse to these means is somewhat questionable. The actual cautery as well as the thermo-cautery present the not unimportant drawbacks that they must be heated before being introduced, and unless both patient and practitioner are uncommonly steady, and the passage less tortuous than usual, more parts will be brought in contact with the heated instrument than desired.

In the galvano-cautery, on the contrary, we possess an appliance that answers all possible requirements. It is under perfect control; it does not destroy needlessly; it is not heated until in contact; it is comparatively painless, and if employed with ordinary care it need be followed by no evil consequence.

The method of employing it in the chronic variety is somewhat thus: After introducing the knife as far back as possible, to turn on the current, drawing the electrode slowly forward, steadily pressing its cutting edge against the hypertrophy, thus scoring the tissue. This may be done several times at each sitting. The good effects that follow are not only the result of the contraction of the mucous membrane, binding down, as it were, the enlarged venous sinuses, but also the dividing of a number of minute superficial vessels bloodlessly at each passage of the knife, while at the same time but little sacrifice of tissue is engendered.

In the acute variety the procedure is somewhat different, and for this reason: in those so-called cases of hay-asthma, or hay-fever, there exists an unnatural excitability or hypersensitiveness of the nasal mucous membrane, and it is necessary to first allay that before scoring. This is best accomplished by passing the flat of the knife as freely as possible over all the lining membrane within easy reach, and thus proceeding to incise deeply in a linear manner as before described. That summer catarrh has no *peculiar* relation to either the pollen of hay or of the rose, or to any other spore or animal exhalation, is now pretty well acknowledged. If any additional proof be needed to strengthen this view, it may be found in the fact that all manner of treatment based upon the spore theory, heretofore introduced, has ignominiously failed, and the treatment by galvano-cautery has been as uniformly successful.

The beneficial effect of high elevations in this sadly misunderstood complaint is not that it frees the membrane from contact with irritating substances, but may safely be attributed to the influence a rare atmosphere has in unloading the local apoplexy, thus rendering the membrane less irritable. I have had under observation a case where a lady, the subject of hay-fever, thrived amid four hundred acres of timothy, and on returning to the city was forthwith attacked by her old enemy.

Of the various tumors likely to be met with in the naso-pharynx as obstructions to nasal respiration, there may be mentioned the gelatinous, polypous, and the fibroid —the former very common, the latter rather rare. The usual method of removal of the myxomatous variety by forceps is somewhat objected to popularly, especially if it has been once undergone. The forceps oftentimes is the best means, however, of reaching the growths, excepting perhaps the various snares, properly curved and armed with a special wire. These snares can be introduced painlessly, and the growth engaged in the loop, gradually working up its pedicle and running it close to its attachment. An application of the galvano-cautery now will prevent any likelihood of return. The fibroid tumor, though capable of removal by the forceps, can be best cut through at its origin by the galvano-cautery wire ecraseur, and whatever pedicle remains may be effectually destroyed by an application of the electrode. A simple method in the myxomatous variety is to pass the knife through and sear up the body of the tumor, thus exposing the pedicle to view, and leisurely proceeding to cut it from its attachment with the same instrument. This method has also the advantage of being painless.

One peculiar feature I have observed is the difficulty, and, I may say, the danger, attending the use of anæsthetics in subjects of nasal or naso-pharyngeal tumors, when nasal breathing is impossible or very difficult.

M. A. C—— came under notice December, 1882, complaining of suffocative attacks on retiring for the night. On examination of larynx, congestion was found; pharynx also involved in the hyperæmia. A posterior rhinoscopic examination was impossible, owing to spasmodic action of velum and attacks of difficult breathing. Anteriorly, nares were found congested; anterior illumination showed at posterior orifices a white, glistening surface, visible through both nasal passages. A probe passed was opposed by a partially yielding body, preventing the further passage into the vault. This difficulty was reinforced by recurring spasm of the soft palate packing up the space. Tumor was diagnosed. All efforts with forceps used posteriorly were rendered futile by the spasmodic action of the velum and choking on the part of the patient. Snares were borne heroically, but all attempts, even with the finger passed behind, were unavailing in engaging the growth, though frequently repeated. Education of the pharynx was equally unsuccessful. On June 7, 1883, assisted by my friend Dr. Roddick, chloroform was administered, and so badly borne that inversion and drawing out of the tongue, which had been swollen, were practised, the jaws requiring first to be forced open. Some minutes later, by passing my finger up behind the palate and directing the palmar surface backward, I succeeded in forcing the tumor against the pharyngeal wall, and by steady pressure downward tore it from its attachment. Bleeding was very free. The growth proved to be a fibroid, and was on its anterior surface bilobular, intimately adapting itself to the nasal orifice, while posteriorly it was spherical, giving a cast of the vault.

The galvanic cautery was applied under chloroform (which was now well borne) to the base of the tumor.

An examination a year afterward developed no recurrence. The principal difficulty was referred to the left subclavicular region, and flattening was undoubtedly present, but no sign of dulness or other organic change was observed.

A second case, W. M——, male, aged seventeen, was referred to me at the Throat Clinic of the Montreal General Hospital, by Dr. Roddick. In this case the right nostril was the seat of attachment. The tumors showed from the anterior nares, and the auriscope and finger developed the fact of extension into the pharyngeal space. They were found to be attached to the middle turbinate. Two were removed by forceps anteriorly, and the third and largest one was pried backward as described in the former instance. Bleeding was free, but easily arrested. These growths gave rise to difficult breathing and asthmatic attacks, with occasional bronchitis, for over two years. The cautery was used a week later to the field of attachment.

Œdema of the septum, diagnosed by rhinoscopy, is easily overcome by either passing a long needle, made for the purpose, through all tissue necessary for removal, and afterward passing the cold wire down over and cutting through; but still more simply and expeditiously with the galvano-cautery knife, one or two sittings accomplishing the task painlessly and effectually. Overgrowth of the erectile tissue of the lower turbinated bone sometimes causes an obstruction to breathing, acting almost after the fashion of a valve at the posterior orifice of the nasal passage. I have removed a pair as large as small plums, that were the provoking cause of one of the most severe attacks of asthma I have ever seen. For the removal of these bodies the cold wire straight écraseur is best and most satisfactory, although using the curved electrode from behind the velum has answered well when from deviation of the septum or other causes a snare could not be passed by the anterior nares.

Adenomata of the vault may greatly obstruct nasal breathing, and need instrumental interference. In early childhood, when they are soft and numerous, they can generally be easily scraped off with the finger-nail. In the adult they become more tough, when forceps, snares, or the hooded galvano-cautery, become necessary. These growths are very common, and are very frequently associated with hypertrophy of the buccal tonsil. They may be looked upon as the result of anterior nasal disorders, and secondary to them. The tonsil of Luschka tends to atrophy at adult life, unlike the buccal tonsil, so that we may safely and truthfully say, in so far as the Eustachian tonsil is concerned, that *the child will outgrow it*, a statement often—unfortunately too often for the well-being of the child—made use of with regard to the buccal tonsil. The buccal tonsils, when hypertrophied, offer an obstruction to nasal respiration often more by their backward pressure on the posterior palatine pillars than by reason of their bulk. When the enlargement is very great, both oral and nasal breathing is impeded; this is the cas · especially in the recumbent position.

In 1828 Dupuytren noticed the frequency of chest deformity in cases of enlarged tonsillar glands. Chassaignac, in 1843, observed that although increased effort of the diaphragm neutralizes to a certain extent the impediment to respiration offered by enlarged tonsils, there are frequent intervals when the power of this muscle becomes temporarily exhausted, and the oxygenation of the blood is very incompletely performed.

Both these observers attributed the ill effects of enlarged tonsils to the fact that they impeded the entrance of air into the lungs, and not to the real cause, namely, the prevention of air entering the lungs from the nasal passage above. The pharynx is sufficiently spacious to admit of a volume of air much greater, even if seriously obstructed by enlarged tonsils, than could possibly pass through the narrow anterior and posterior nasal orifices.

The spacious mid-chambers of the nose were intended for the purpose of preparing atmospheric air for healthy lung respiration, and have no influence whatever on the quantity capable of being transmitted through the nasal passages. As to the wisdom of the so-called extirpation of the tonsils, when they act as mechanical impediments to respiration, there seems to me to be no doubt. The various fears entertained concerning the influence of their ablation on general development are purely chimerical.

I do not think I exaggerate in saying that in one hundred and forty-two tonsillotomies performed by myself the patients or their friends had reason to regret the results obtained by its performance. Surgical interference is the only means of satisfactorily getting rid of these abnormal growths, and it has seemed quite safe in its performance. I have had one hemorrhage, not a very severe one, more the result of the obstinacy of the patient than of the operation. The tonsillitome is the safest, best, and most expeditious means of operation, and an instrument after Physic's pattern is much to be preferred. Rest in the recumbent position should be enjoined for four or more hours afterward. Crushed ice should be used freely, and an astringent of tannic and gallic acid applied. Bearing in mind the possibility of hemorrhage, and taking the precaution for the prevention of it, will surely go far to render the liability to it, however little, less.

It is generally but not always necessary to remove both tonsils. A curious fact, call it a coincidence if you will, observed during the last epidemic of diphtheria was, that in not less than three subjects in whom it had been necessary that but one tonsil should be removed, no exudation occurred on the surface of the ablatized tonsil, and but very little in its vicinity. This was very well marked in one case, a very severe one, which was seen daily by Dr. Browne and myself for a period of over three weeks. The membrane, though uniformly spread over both sides, avoided entirely the cicatrized surface, and yielded much more readily in its neighborhood. Possibly the relief of the parts from the irritating presence of the enlargement had some influence in this direction.

In conclusion, I may be permitted to say, and it is a verdict that has not been arrived at hastily, that the very best means possible for preserving a healthy chest and throat are to be found in nasal respiration. In fact, a being who breathes as nature intended should not suffer from any throat affection, or at all events should enjoy considerable immunity therefrom. Bronchial asthma is most common in mouth-breathers, and mouth-breathing is as hereditary as asthma. I do not go too far when I assert boldly that a healthy state of the lining of the pharynx, larynx, and lungs is incompatible with any form of respiration but the nasal. I have thus briefly and incompletely endeavored to draw your attention to what I am free to consider one of the prevailing disorders of the day. I do not claim to have announced anything new, but rather to have emphasized our duty to society in regard to this most important but elementary point.

Nephrectomy for Calculous Pyelitis.—Dr. A. Salomoni (*La Gazetta degli Ospitali*, August 31, 1884), reports a case in which Professor E. Bottini, of Milan, successfully removed the kidney. The patient, aged twenty-seven, had had two calculi removed by lateral lithotomy fifteen years previously. Three years after that operation an abscess formed in the right iliac fossa. It opened spontaneously, and after a few months reappeared in the lumbar region, when it was opened with caustic potass. A permanent fistuala resulted, and proved intractable to all local and constitutional treatment. The patient lying on the left side, under chloroform, Professor Bottini, under strict antiseptic precautions, made a vertical incision through the whole ilio-costal space, three inches outside the quadratus lumborum. The kidney having been isolated, the renal artery was secured in one ligature, the vein and ureter in another. The space having been well cleared and all bleeding stopped, a drainage-tube, about one-third of an inch in diameter, was introduced. The walls of the fistula were excised, and the wound united by one deep metallic suture and eight superficial silk ones. The operation lasted a little over an hour. The antiseptic dressing was renewed daily, the metallic suture was removed on the third, and the silk ones on the fourth day, when the drainage-tube was shortened. It was withdrawn on the eighteenth day. Progress was uninterrupted. The highest temperature, 99.5°, was reached the second day; urine in normal quantity and without deposit was passed without pain or trouble. The patient left his bed on the sixth, and went home the eighteenth day, when only a slight sinus remained, about an inch deep. The fistula led into the pelvis of the kidney, which was dilated, with thickened and suppurating walls, and contained, beside some uric-acid sand, two small calculi about the size and shape of grains of barley.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 22, 1884.

ON THE LIMITATIONS OF THE KNOWLEDGE REGARDING CHOLERA.

IT is only by constant reiteration that knowledge is finally inculcated and public opinion affected. In this we find a justification for the frequent and discursive contributions to the subject of cholera which are at present filling the columns of the secular and medical press. The inquiring reader begins each article with fresh expectation of enlightenment. But all the knowledge of our most erudite sanitarians and eminent pathologists seems reducible to this: that cholera is communicable and portable, that it affects filthy localities and people, that rigid municipal and personal sanitation, and a discriminating use of quarantine measures should be enforced.

That there is some kind of a cholera germ all believe, but what it is none know. It has been very generally agreed that this germ requires a special nidus for its development, that for the spead of cholera there must be a something which has been called "epidemic constitution." But modern sanitary reformers assert that this so-called "constitution" is only an intensity of filth. In the city of Hygeia there are no epidemic constitutions. And such is the safest practical view to take, whether it be an absolutely true one or not.

As for quarantine, some dissenting voices here echo the English opinion as to its non-utility. We had best go, however, by what our past experience has taught us, and that is, that quarantine is a valuable means of protection. It should be applied sensibly and with discrimination, however, and should bear most of all upon the immigrants, who have heretofore been the primary dispensers of the hypothetical bacilli of cholera in the United States.

The cholera germ may be positively discovered any day, meanwhile Koch's bacillus theory has not, as was first hoped, thrown any flood of light upon cholera problems, and as for its prophylaxis it is still expressed in these three phrases: *Rational quarantine, municipal cleanliness, personal hygiene.*

REGULATING MEDICAL PRACTICE IN MISSOURI.

THE stirring attack made some time ago by Dr. King upon quackery in Missouri has already borne fruit. The State created a board of health in July, 1883, and gave to it a certain amount of power in regulating medical practice and putting down quackery.

The provisions of the law are much like those of Illinois, and it contains the "itinerant quack" section compelling travelling venders of nostrums and persons publicly professing and advertising to cure disease to pay a monthly license of $100 Attempts to enforce such a section naturally create some trouble, and we learn from the Kansas City *Medical Index* that the efforts of the State Board to enforce the law in that place have been violently opposed by the quacks and the public press—two social forces which often work harmoniously together by reason of the profits of advertising.

The *Index* puts the matter very fairly: "The law calling into existence the Board and also governing its action was enacted for the benefit of the public, and not for the benefit of physicians, as some of the papers try to represent. These papers receive large amounts of money from these pretending doctors for advertising, and hence they cry out because their ox is gored."

We would remind the *Index* also that the creation and enforcement of regulating laws is based not only upon the need of protecting the public health and of purifying the medical body, the State of Missouri obliges medical men to report all births and deaths, thus giving to them an official duty and in a measure an official position. The State, on this ground, can rightly insist on passing upon the qualifications of its medical practitioners.

THE MEETING OF THE NEW YORK STATE MEDICAL ASSOCIATION.

THE New York State Medical Association held a pleasant and harmonious meeting in this city during the past week. The attendance was very good, especially of out-of-town physicians. The medical contributions, though not destined to make new epochs in science, were, many of them, of excellent character and likely to reflect credit upon the State. Indeed, it is a matter of some pride to New Yorkers to find that the State can creditably support and contribute to two organizations.

New York City is a pleasant and alluring place for medical meetings, and so long as the Association assembles here, and does good work, it will receive support from and be a source of benefit to its members. The issue which started it is already nearly forgotten, and sensible men recognize that its practical significance is now trivial. It is not upon any point in casuistry that the Association can stand or hold together, but upon its merits as a medical society.

THE UTILITY OF QUARANTINE IN CHOLERA.

DR. JOHN H. RAUCH takes the view that cholera is preeminently a quarantinable disease, because "no single case of cholera, no one shipload of cases has ever yet sufficed to establish an epidemic of Asiatic cholera on this continent. It has only been after repeated importations of the contagion in the persons of thousands of immigrants and in their infected baggage and household goods that it has effected a lodgment, and has reproduced itself and multiplied into an active epidemic agency."

In proof of this he cites the history of previous epidemics of cholera in this country. Dr. Rauch appears to forget, however, that, even if his facts are correct for the United States, in the past they do not fit the history of

cholera elsewhere. And the proposition that an epidemic of cholera can not be started by a single case is utterly untenable.

For all this cholera is undoubtedly quarantinable, and if Congress will do its duty there is a good chance that the disease may be kept from us.

News of the Week.

Death of Dr. Samuel M. Bemiss.—We regret to announce the death on November 17th of Dr. Samuel M. Bemiss. He was Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Louisiana, and during the epidemic of 1878 was the representative of the National Board of Health in New Orleans. He was sixty-three years old, and served as a surgeon in the Confederate Army. He was a graduate of the medical department of the University of New York.

Cholera and Rags.—Experience shows that cholera has been brought to this country heretofore by passengers, and especially immigrants and their baggage. It is very certain, however, that the disease can be carried by rags and this source of danger ought to be carefully watched. A complete embargo on rags from all ports or even a compulsory disinfection of them is unnecessary.

State Medical Association Notes.—It may happen that the New York State Medical Association, which met in this city during the present week, will prove to be an agent of value to the State Society and the profession at large. At least the Society may learn from it several lessons. One of these is that New York City is an excellent place in which to hold annual medical meetings. Taking it all in all, the means of reaching it are as good, if not better, than those of reaching Albany, while the accommodations and general attractions are superior.

The Association has shown also that by energetic work papers can be obtained from physicians all over the State, and that the bulk of the literary work need not fall upon New York City.

As for the Association doing any injury to the State Society, this is not to be thought of, and is not probably intended except by the embittered few. The rural practitioners throughout the State recognize the slight practical importance of the ethical issue, and feel no ill-will toward the Mother Society, which has what the Association has not, a past. Perhaps this is in no way better shown than by the indifference felt toward the fact (for it is a fact of which there is absolute proof) that the President, Dr. Didama, has consulted with homœopaths, excusing the practice under the disingenuous plea that he treats the homœopaths who call him in as nurses.

The papers read at the Association were in many cases too long, and little chance was given for profitable discussion. The question of section meeting was naturally raised; it is one that the State Society has considered and will doubtless have in time to adopt.

Dr. Samuel A. Fisk, aged sixty-three, ex-President of the Massachusetts Medical Society. Lecturer at Smith College, and Trustee of the Clarke Institute for Deaf Mutes, died at Northampton, on November 16th, of organic disease of the heart.

Pennsylvania Hospital.—On November 10th, says the *Philadelphia Medical Times*, a notable ceremony was held at the Pennsylvania Hospital, the occasion being the restoration, after an absence of fifty years in another department of the institution, of the celebrated picture of Christ Healing the Sick in the Temple, which had been originally painted for and presented to the hospital by Benjamin West.

A Mistake.—Our usually careful contemporary, *The Boston Medical and Surgical Journal*, states that the New York County Medical Society unanimously voted to admit to membership two homœopaths. This is a mistake. The gentlemen in question have distinctly renounced dogmatic homœopathy.

Death of a Physician from Self-Administration of Chloroform.—It is a practice which we fear is not very uncommon among physicians to inhale chloroform when suffering from severe pains. The *Weekly Medical Review* reports the death through this practice of Dr. C. M. Whiting, of Ogle County, Ill. Reference is made also to the death some years ago, in a similar way, of a young physician who had just graduated and was practising in the suburbs of Chicago.

The Cholera in Paris.—Cable reports show that from forty to fifty deaths from cholera occur daily in Paris. This represents about one hundred cases daily, and indicates a considerably less prevalence of cholera than often exists of diphtheria, or typhoid fever. There is no panic, and the disease at date of writing is declining.

A Crematory for New York.—The corner-stone of a crematory temple was laid at Mount Olivet, Long Island, on November 20th. The proposed edifice is being built by the United States Cremation Company, which expects to complete its work by February next. Twenty bodies already await incineration. The cost of the building is about $10,000, that of incineration $10 to $25. The building is in the shape of a Greek temple 40 by 72 feet. Incineration will take place at a temperature of about 2,500° F. It will require about forty minutes per hundred pounds of the subject, and will leave about four per cent. in weight of a pure pearly ash. No smoke will be visible and no odor perceptible during incineration. The basement will also contain a *refrigidarium*, where bodies may be kept when desired awaiting the arrival of friends from a distance; also a *calidarium* for cases of possibly suspended animation, the high temperature of which will induce speedy evidences of life or death, as the case may be. There will be, also, in the basement an *ædicularium*, or urn room, and an atelier. This last will be used, also, for making autopsies, which will be required in all cases wherein it is not clear that death is the result of natural causes. The body of the building, or the ground floor, will be fitted up as a chapel, where any service desired may be held.

A Contribution Toward the Medical Education of Women.—The Calcutta Medical College has received from the Maharani Surnamayi of Cossim Bazaar, Moorshedabad, one of the millionaires of Bengal, a lakh and a half of rupees, $75,000, toward the scheme for providing separate classes for female medical students at the College, and has promised to increase the gift to eight lakhs ($400,000), should a separate college be provided.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

First Annual Session, held in New York City, November 18, 19, and 20, 1884.

TUESDAY, NOVEMBER 18TH—FIRST DAY—MORNING SESSION.

THE Association was called to order at 9.45 A.M., by Dr. Gouley. The Secretary announced the registration of Fellows. The Chairman of the Committee of Arrangements, Dr. Gouley, then welcomed the Association in a short address.

THE PRESIDENT also delivered an address, and announced the following as the Committee on Scientific Contributions: Dr. E. S. F. Arnold, of New York County; Dr. Simeon T. Clark, of Niagara County; Dr. William Gilles, of Franklin County; Dr. George W. Avery, of Chenango County; Dr. J. C. Hannon, of Rensselaer County.

The Secretary then read the report of the Council, and on motion of Dr. Arnold the report was adopted.

Representatives from the Vermont Medical Society and the Pennsylvania State Society were received.

The annual report of the Treasurer was made and accepted.

The special committee on the organization of district associations reported in favor of the establishment of five such associations. After some discussion the report was adopted.

THE ADDRESS ON SURGERY

was then delivered by DR. E. M. MOORE, of Monroe County.

The object of the paper was not to enumerate all the late discoveries in surgery, but to dwell upon a few facts in connection with transfusion of blood. Various methods of transfusion have been proposed, but none have given general satisfaction. When first discovered great expectations were founded on it, but on account of some unfortunate accidents the practice was condemned. That it has great value cannot be disputed. All surgical practices to be successful must be simple. Complicated apparatus is to be discarded and some simple surgical device instituted. In 1657 Sir Christopher Wren suggested the possibility of this practice. At first it was tried only on animals. These experiments were the natural outcome of Harvey's discovery. Some denounced the practice as legalized murder. After 1668 the interest seems to have disappeared. Up to 1819 only arterial blood was used, but since, all kinds have been employed. The blood of those species nearest of kin has been most successfully used. Transfusion from the lamb to man has been more or less successful, but blood obtained from the same species answers best. We cannot obtain arterial blood from human beings, and hence must take venous. To avoid danger from coagula, defibrinated blood is sometimes used. The question was raised whether this was true blood, and answered in the negative by the author. Various medicated substances have sometimes been used, but blood answers best. The distention of the vessels by simple saline solutions has at times given temporarily great benefit. The principal dangers of transfusion are from ingress of air and formation of coagula. The special point made by the author was that the time of operation should be short and definite. Most operators take from two to three minutes. *The operation should never exceed the limit of one minute.* There is a period of transition from normal blood to abnormal during the passage through the canula, hence the absolute rule of shortness of time. An assistant should read off ten seconds, twenty seconds, thirty seconds, etc., during the operation. The transference of venous blood is a difficult problem. A longitudinal slit should be made in the vessel and the syringe held perpendicularly. The writer then exhibited a canula and mandrel devised by himself, which has been successfully used. By rounding the edges coagulation is prevented. The instrument can be extemporized in case of emergency by using a goose-quill for a canula. Dog's blood coagulates quicker than human blood, but the author had succeeded in experiments with his instrument upon the dog. Transfusion is especially indicated after sudden great losses of blood, and in anæmia from exhaustive discharges. It does not seem to avail in the exhaustion from phthisis and like diseases.

DR. TOWNSEND, of Genesee County, opened the discussion by narrating an instance in which Dr. Moore and himself had practised transfusion in fifty seconds. The operation was successful at the time, but the patient afterward died of exhaustion. It was then moved and carried to postpone the further discussion until after the reading of Dr. Hutchinson's paper on transfusion.

DR. DETMOLD, the president of the County Medical Association was then introduced to the meeting. He stated the objects of the Association and announced the titles of the papers that had been read during the past year. It was carried to transfer these papers to the Council of the State Association.

A recess was next taken, during which there were meetings of the five district associations, in which the time and place of next meeting were appointed and secretaries named.

AFTERNOON SESSION.

The Association was called to order by THE PRESIDENT, who remarked that it might be necessary, owing to the large number of papers announced, to divide the work between two sections, a medical and a surgical. This would be determined by the members during the present session.

The first communication was by DR. J. C. HUTCHINSON, of Kings County, upon

TRANSFUSION.

Although this operation had been practised five hundred years ago, it was still but rarely undertaken, and had certainly not fulfilled its early promises of utility and ready applicability. The present epidemic of cholera in Europe has invested the subject of the transfusion of blood and other substances with fresh interest, and the author believed that the procedure might now become popularized were the means of its application simplified, the dangers diminished, and the apparatus improved. An instrument was then exhibited which seemed to fulfil the indications of simplicity and ease of management. It consisted of a glass cylinder, terminating below in a perforated metal cap, and above in a rubber stopper through which was inserted a thermometer. The side of the cylinder was marked off in sections of half an inch. Surrounding the cylinder was a double rubber jacket with a slit on one side to permit a view of the markings on the glass. This rubber jacket was to be filled with hot water (of 140° to 150°) in order to keep the injecting material warm. A rubber tube is fastened to the lower end of the cylinder by one extremity, the other extremity being attached to a canula. This canula is provided with a stop-cock by means of which the rapidity of flow of the transfused material is regulated. The author had not seen the instrument exhibited by Dr. Moore before writing his paper, but thought it excellent, and should himself always use the canula there shown.

It was formerly supposed that the reviving power of transfused blood lay in its corpuscles, but this has been shown to be erroneous, for the corpuscles are quickly destroyed. Recent experiments have demonstrated that the principal thing necessary is to restore the volume of the circulating fluid. The danger after hemorrhage lies in the disturbed relations of the blood-vessels to their contents, hence it is not necessary to employ blood, and indeed a saline solution is preferable. Experiments have shown that the blood of another species, when injected

into the circulation, may cause acute nephritis and imperil life. Milk is objectionable, for the undigested casein when transfused into the blood is unassimilable, and the butyric elements may give rise to chyluria and other disturbances. Experiments made upon animals bled to syncope have shown that consciousness could be restored and life preserved by the injection of simple saline solutions, and the value of this material for transfusion has also been demonstrated clinically. The author quoted the statistics of the transfusion of saline solutions, and related five cases in which he himself had employed this method in the resuscitation of cholera patients. All the patients were in the stage of collapse, indeed were moribund. The temporary effects of the transfusion, however, were most marked, although all the patients eventually died.

The temperature of the solution should be not lower than 98.5° and not above 105°. The quantity used should be from twelve to twenty-four ounces. But one of the most important points in the operation is the rapidity with which the fluid is allowed to enter the vessels; the rate should not be above one ounce a minute. The median basilic vein is usually selected to receive the transfused material, though lately arterial injections have been urged as offering equal facility, and obviating the chief danger of embolism of the brain (since all organic particles or clots are detained in the systemic capillaries), of the entrance of air, or of overpowering the heart by a sudden afflux of fluid. In concluding, the author said that if the results already obtained by transfusion should be confirmed by further experience, the operation was one deserving of more honor than it had as yet obtained.

Dr. Rochester, of Erie County, related a case in which a speedy and permanent improvement had followed upon the transfusion of less than two ounces of blood, and he thought that this demonstrated that it was not alone to the quantity of fluid that the good effects of transfusion should be referred, but that the nature of the material employed was also to be considered. He also had seen wonderful improvement following the injection of saline solutions in the stage of collapse of cholera, but these results were only temporary, for the patients invariably died.

The next paper read was by Dr. Alfred L. Carroll, of Richmond County, on the

DURATION OF CONTAGIOUSNESS AFTER ACUTE INFECTIOUS DISEASES.

The object of his remarks, the speaker said, was rather to direct his hearers' attention to the importance of studying this subject and recording their observations by the plan of collective investigation, than to present any certain data upon which they could yet base their conduct in any given case. The subject was one that had received but scant attention, and upon which there was but little unanimity of opinion, and yet a little consideration would show how important it was to be able to determine just when the isolation of a convalescent might with safety be removed. The author had addressed a communication to a number of well-known medical teachers and practitioners, in order to ascertain whether there were any consensus of opinion on this point, and he presented to his hearers a condensed summary of the answers obtained. As regards small-pox, nearly all of his correspondents were agreed that there was danger of contagion until all the crusts had been removed, although one stated his belief that there was little danger to be apprehended from the scabs on the palms and soles, provided there were none remaining on the other parts of the body. In respect to the other contagious diseases there was less accord. In typhoid fever and in cholera it was the general opinion that the contagion resided in the discharges, and that the danger ceased when convalescence had been established. Many of the correspondents, with whom the author also agreed, regarded filth-poison as of prime importance in diphtheria, and doubted the existence of a direct personal contagiousness. Yet one writer maintained that there was danger as long as any trace of inflammation remained. In measles one would release the patient from quarantine as soon as the fever and eruption had disappeared, while others would prolong the period of isolation to from one to three weeks after desquamation had ceased. The greatest diversity of opinion existed in regard to scarlatina. Many released the patients as soon as desquamation had ceased and a bath had been given; others confined them for a period varying from six to eight weeks. The author had found in some cases that no contagion occurred even when the children mingled with their playmates before the period of desquamation was over. He thought that this fact was to be explained by assuming that the last scales thrown off were not infectious, but were the expression of a secondary dermatitis, the scales first appearing being the ones that contained the poison.

Dr. John S. Jamison, of Steuben County, then read a communication on

CHRONIC INTESTINAL CATARRH.

The most frequent cause of this condition is an improper diet, as regards either quantity or quality. Another potent factor in the production of the disease is found in meteorological conditions—a prolonged high temperature or a change to cold, damp weather. It may arise from impaired stomach digestion, from disease of the liver or pancreas, or from any condition causing obstruction to the portal circulation. The malarial poison is another occasional etiological factor. An acute diarrhœa is often neglected and may then pass, after successive attacks, into a chronic intestinal catarrh. The symptoms of this condition are not always sharply defined, for diarrhœa is not necessarily present, and there may be no severe pain. There is often a dull sense of pressure and abdominal fulness. The author had frequently observed a displacement downward of the transverse colon, and he regarded it as a sign of considerable value in the diagnosis of this disease. Sometimes mucus, in coherent masses or even in the shape of intestinal casts, is passed at stool. In the treatment the author regarded pepsine and pancreatine as of great utility.

A paper by Dr. Frederick Hyde, of Cortland County, was read by title only, the author being absent.

Dr. Edward R. Squibb, of Kings County, then followed with a paper entitled

THE MODERN PROGRESS OF MATERIA MEDICA.

The author did not refer to the introduction of new remedies, now becoming so fashionable, but rather wished to consider the elements of progress in the treatment of disease among that large class of intelligent and practical physicians who read much but write little, but who are none the less good, sound, and sensible practitioners. The progress of materia medica among these men cannot be learned from their writings, since they do not write, but is to be judged of by knowing the drugs which they order and use. Medical men now realize the fact that their success in their profession depends upon their utility to the public; they must direct their energies to the prevention of disease, to its management when it occurs, and to the reparation of its ravages. The physician does not now rest content with a diagnosis, but seeks as far as he may to conduct his case to a successful ending. We hear less and less of expectancy in the treatment of disease; indeed the danger now is of rushing into the opposite extreme by trying all the new remedies that are spoken of. The author pictured the armamentarium of a physician in one of the new Western towns; this consists of a thermometer, urinometer, litmus paper, often a plain serviceable microscope, and sometimes even a sphygmograph. He has a good selection of some twenty or thirty of the standard remedial agents, but few non-officinal drugs are found in his stock. More pharmacopœias are sold now than formerly, and physicians are

learning to make their own tests and to judge for themselves of the purity of the drugs supplied to them. Few physicians nowadays undertake "cures," but they endeavor to conduct the disease to a successful issue. Few believe that drugs cure diseases, and hence they seek to manage their cases according to the indications as they arise. Another advance that has been made in the last few years is, that practitioners are learning to throw off the trammels of arbitrary doses. They now look only for *effects* from remedial agents, and they accordingly push the drug until they obtain these effects. The use of indicating doses for drugs, the writer thought, will in the future be only to show where we are to start in their administration, the stopping-point being different in different cases, and to be determined only by observation of the effects produced. Physicians use fewer drugs than formerly, but those that they do use are more effectual. The combination of many agents in one prescription is less frequently resorted to. The form of the agent now used is also worthy of note. The dilute and uncertain preparations are being called for with less and less frequency, and the fluid extracts, as the most concentrated and most reliable forms, are growing daily in favor. There is, however, a tendency to the use of alkaloids, of the so-called active principles of drugs, which the author did not approve. The active principles so-called, he maintained, are not the same as the drug, for they are often produced by some chemical change occurring in the course of their manufacture. They are furthermore not always permanent, but are liable to split up and form new chemical compounds with totally different effects. Thus, the author concluded, although in the main the progress has been in the right direction, yet not all the changes of late have been improvements.

Dr. W. H. Robb, of Montgomery County, read a paper on the

MANAGEMENT OF CRIMINAL ABORTION.

Control hemorrhage as soon as possible with ergot and digitalis given hypodermically and in full doses. Stimulants should be given by the same method until the patient has rallied. The ergot should be given as soon as the patient is seen, and should be continued until the uterus has contracted and the ovum has been entirely removed. Locally, various astringents, as ice, tincture of iodine, hot carbolized solutions, and other remedies, may be used. When these means fail to control the hemorrhage, the tampon should be introduced. The tampon should be removed every six hours, and its removal should be followed by a hot carbolized injection. The injections are best given by introducing a soft rubber tube into the uterus. The Fountain syringe is the best, as by its use no force can be exerted and no air can enter the organ. The womb should be emptied as soon as possible, so that all danger of decomposition may be prevented. The safest and most efficient instrument in removing the ovum is the finger. If the cervix is not dilated, tents should be used. The removal of the ovum should be followed by a hot douche.

Dr. Vandewaker, of Syracuse said the danger in abortion before the third month is due to loss of blood and poisoning from decomposition. He had never seen a good result from the use of ergot in criminal abortion. The machinery of the uterus is not fully developed before the third month, hence the uterus does not contract firmly, but spasmodically. If the physician is called late at night, and no other means are at hand, the tampon may be used; but it should never be used unless absolutely necessary. The quickest way to stop the hemorrhage is to relieve the uterus of its contents.

Dr. Moses C. White, of New Haven said the action of ergot in abortion at the third month is not to expel the contents, but to contract the uterus and thus prevent its expulsion. He uses ergot, not to bring on but to prevent abortion.

Dr. Sabine, of West Point, explained the dangers of using the tampon, and gave the history of a case of rupture of the fundus of the uterus, followed by the death of the patient, due to its use. Tampons are very dangerous unless used with great caution.

A paper on

INTESTINAL OBSTRUCTION,

by Dr. Avery Segur, of Kings County, was then read by title.

Dr. Charles Bulkley, of Monroe County, read a paper on

CHRONIC MERCURIAL POISONING.

He presented the history of a case in his own practice in which the poisoning was due to wearing a hard rubber plate with false teeth. All the symptoms were present while the plate was used, but disappeared when its use was discontinued. He also presented the histories of several other cases due to the same cause.

Dr. R. H. Sabin read a paper on

A CASE OF ACUTE LEAD POISONING RESULTING FATALLY.

The case was that of a young man who was poisoned while working in a paint shop. There was a rapid infusion into the brain, causing insensibility, and this was followed by a peculiar algid condition.

The session then adjourned until evening.

Evening Session.

Dr. H. E. Mitchell, of Rensselaer County, read a paper on

ERRORS OF REFRACTION, THE IMPORTANCE OF THEIR RECOGNITION AND CORRECTION IN EARLY LIFE.

Defects of eyesight due to errors of refraction are on the increase. A description of the coats of the eye and the contents of the ball was then given. Myopia may be acquired or congenital. Statistics show an increase of the congenital form. The acquired is the most important to consider. The minus or double concave glass should be used. Myopia in young persons shows a tendency to increase.

Dr. E. D. Ferguson, of Rensselaer County, read a paper on

THE USE OF THE ASPIRATOR IN HYDROTHORAX.

A case was cited in which after several aspirations were performed for pleuritis, empyema set in. The author has had three such cases. He now abstains from aspiration unless the dyspnœa is extreme. When the operation is performed only a slight amount of fluid should be abstracted. Since following this rule, he has not had a case of empyema in practice. The innocuousness of the operation is assumed by most text-books, the only warning being to stop when there is constriction at epigastrium. By suddenly emptying the chest of fluid, support is taken from the vessels, which results in increase of blood with resulting tendency to suppuration. Eight ounces is the greatest quantity that should be taken at one time in pleurisy.

Dr. Thomas F. Rochester, of Erie County, next read a paper entitled

A NEW PROCEDURE IN PARACENTESIS THORACIS.

The histories of three cases of empyema were given, in all of which there was great difficulty in enlarging the incision sufficiently to hold a tube. The doctor has found that by inserting his finger into the incision and thus enlarging the opening, all such difficulty is overcome.

Dr. Austin Flint did not believe that the aspirator caused as much damage as claimed by Dr. Ferguson, although doubtless it sometimes did harm.

Dr. Moore thought that all surgical instruments occasionally did harm. In empyema the best practice is to draw off a little pus each week by the aspirator. In abscesses, the walls of which cannot contract, all pus should not be drawn out at once.

Dr. Rochester thought that from eight to ten ounces

were enough to take out at one time. He believes in the drainage tube, and has had no success with fistulous openings.

Dr. Feifield, of Boston, has used his finger to enlarge the opening in empyema for some time.

Dr. Austin Flint, of New York, read a paper on the

DIETETIC TREATMENT OF DYSPEPSIA.

Some authorities give the term dyspepsia as synonymous with the term indigestion; but he maintained that the term dyspepsia denotes an affection distinct from indigestion. He then gave the local or stomach and general symptoms of the affection. The appetite may be impaired, but is sometimes increased. The mind plays an important part in the etiology of the affection. The old method of treatment was to strictly regulate the diet, drink very little or no fluids, and always leave the table hungry. Such treatment is entirely wrong. Dyspepsia may be developed by the attempt to regulate the diet by rules intended to prevent the affection. I always ask a patient, Do you regulate your diet? and he always answers in the affirmative. I have never known a dyspeptic to get well who attempted to regulate his diet. Regulate by the appetite, the palate, and by common sense. A patient may ask, Am I not to be guided by personal experience and avoid such articles as I have found to disagree with me? I answer that personal experience is very deceptive. An article that would disagree to-day would agree to-morrow. Do not adopt the rules of eating only twice or thrice a day. Be governed by the appetite. Those articles are most digestible which are most acceptable to the palate. Do not leave the table hungry. Take animal and vegetable products, and drink according to the want of instinct. The diet which in healthy subjects is conducive to health is the best diet for dyspeptics. It is a fallacy to suppose that in dyspepsia the organs of digestion need a prolonged rest. Patients should not be afraid to rely upon their digestive powers. Perfect cures have been obtained by following the instincts of nature. Dyspepsia is most common in the better educated classes, because they endeavor to regulate their diet on scientific principles.

A paper on

DOUBLE SYNCHRONOUS AMPUTATIONS

was read by Dr. W. C. Lynde, of Erie County, in which he presented the statistics of a large number of cases.

The same writer then read a paper on the

FUNCTIONS OF THE AURICLES.

He maintains that the auricles do not contract, and that a suction force is exerted on the part of the right ventricle.

Dr. Austin Flint, Jr., said although the walls of the auricles are much thinner than the walls of the ventricles, they are composed of muscular tissue, and do contract. He had seen them contract many times in operations on the lower animals. In man there are no valves guarding the openings of the veins into the auricles. The contraction of the muscular fibres constricts the openings of these veins and prevents the regurgitation of the blood. He does not believe in the suction force of the ventricles.

Dr. Austin Flint, Sr., described the contraction of the auricles and the production of a heart-murmur which was caused by the contraction.

Dr. Moore, of Monroe County, described some experiments made by him and others in 1838, at a time when we knew little or nothing of heart disease. This was the starting-point of our knowledge of heart-sounds. The contraction of the auricles is as easily seen as the contraction of the ventricles. It requires simply to be looked at in order to be known.

Dr. Austin Flint described the jugular pulse as due to the contraction of the right ventricle and also to the contraction of the auricle. The presystolic murmur is due to the contraction of the auricle and is produced, not by a passive flow of blood from the auricle to the ventricle, but by an active force.

Dr. Ross related a case of rupture of the right ventricle, from which he argued that the force to produce this result must have been due to the contraction of the auricle.

The President asked

WHAT WAS THE USE OF HAVING A MUSCLE IN THE WALL OF THE AURICLE

if it had no action?

Dr. Lynde closed the discussion. He had many times experimented on different animals, by introducing a canula and trochar directly into the auricle, and had never seen the blood well up in the canula, while, when the same instrument is introduced into the ventricle, the blood is thrown to some distance. It would not do to have the veins empty directly into the ventricles.

Wednesday, November 19th—Second Day—Morning Session.

The Association was called to order at 10 A.M.

Dr. Gouley suggested a plan that the Association should have

A CITY HEADQUARTERS, A PLACE THAT COUNTRY MEMBERS COULD REGISTER AT.

This would include the founding of a library under the direction of the Council. There was already formed the nucleus of a library, and forty journals had been promised. He further suggested that a voluntary fund be started, to be divided into a library fund and a sinking fund, for putting up a building. This plan was put in the form of a motion.

Dr. Moore seconded the motion, and stated that the desirability of such a plan was obvious, although there might be pecuniary difficulties.

The resolutions were carried.

It was then carried that

THE LETTERS "F.S.M.A." PLACED AFTER A NAME IN ANY SCIENTIFIC PAPER SHOULD BE OFFICIALLY KNOWN TO REPRESENT THE ASSOCIATION.

Dr. S. B. Hubbard, of New Haven, and Dr. H. B. Ransom, of Iowa, were invited to sit as delegates.

Dr. Allen, of Rensselaer County, read a paper on

DIARRHŒA FROM DISEASE OF THE PANCREAS.

The history of a case was given that the doctor called

ADIPOSE DIARRHŒA,

in a man about sixty years of age. The stools were not very fluid, but contained matter looking like melted fat. There was pain at umbilicus and borborygmi just before the stools. The patient had three or four movements a day, the odor of which was unbearable. The fæces presented bundles of fasciculi surrounded by fat; appetite variable. Pepsine and pancreatine, āā. gr. v., t.i.d., and an opiate constituted the treatment. For diet, soft-boiled rice, milk, toast, and tea. Under this treatment there was less adipose matter in the stools. There was coldness of extremities noticed to be present. The patient improved, but had a relapse from eating pork. He grew rapidly worse, and sank into a deep stupor; urine partially suppressed, and an examination showed one-quarter part sugar, one-sixth albumen, with epithelium, hyaline casts, and broken down blood-corpuscles. The patient died in coma and no autopsy was permitted. The case was presented to the Association as a remarkable one.

THE ADDRESS ON OBSTETRICS AND GYNECOLOGY,

was delivered by Dr. T. Gaillard Thomas, of New York.

The author was asked to give an estimate of the present status of obstetrics and gynecology. Obstetrics has always existed as an art, but not as a science. William Hunter first elevated it to the position of a science. Since his time there has been a steady advance. One great advance has been the discovery of the relation of the low monads and micrococci floating in the atmosphere to diseased processes. This discovery has been of as great importance in obstetrics and gynecology as in general surgery. In the parturient process the open

mouths of vessels afford opportunity for the absorption of poison from without. In the near future, antiseptic obstetrics will probably be the rule. It never does any harm, and if only one life in a hundred should be saved, the extra trouble would not be unavailing. To free the parturient act from septic dangers will be to save millions of lives in the future ages. The germ theory has revolutionized the treatment of puerperal fever. Instead of quinine, opium, and poultices, antiseptic intra-uterine injections, containing bichloride of mercury or carbolic acid are now used. Quiet pain by hypodermics of morphine. Lower temperature at once, by a coil of running water. Give a milk diet and perfect rest. Extra-uterine pregnancy is now successfully treated by the fœticide power of the strong galvanic current. The early diagnosis and treatment of tubal pregnancy is becoming more satisfactory. The methods of inducing premature labor have become so safe and practicable that in placenta-prævia, uræmia, etc., it should be oftener resorted to. The obstetric forceps is the most life-saving instrument ever devised in surgery. There have been few real improvements in this instrument. Tarnier has recently made an improvement by adding tractors. Two substitutes have been employed in place of Cæsarean section: Porro's operation and laparo-electrotomy. The writer thinks the results of the latter operation are better and safer. A successful case by Dr. Pilcher was reported. The gynecology of the future will be more allied to surgery than medicine. Instead of applying caustics to an ulcerated os, the lacerated cervix is now sewed up. Trachelorrhaphy has done much good and will do more. Extirpation of the ovary for various causes is now legitimate and useful, although liable to abuse. In uterine deformity the forcible dilatation of the cervical canal is being tried. Among drugs the permanganate of potash is the best emenagogue.

Afternoon Session.

Dr. T. B. Reynolds, of Saratoga County, Vice-President, presided.

The first paper read was by Dr. Darwin Colvin, of Wayne County, on

venesection in the convulsions of pregnant and parturient women.

The speaker based his remarks upon a combined experience of his father and himself, extending over a total period of ninety-two years. Most of the cases recorded in his father's note-books occurred at a time when chloroform was unknown and before albuminuria was heard of, while his own cases belonged to a later period, when anæsthetics were in daily use, bleeding was out of fashion, and the pathology of puerperal eclampsia was beginning to be better understood. In none of his father's cases did convulsions occur when venesection had been practised upon the appearance of threatening symptoms, and even in those in which convulsions had already occurred a prompt withdrawal of blood averted the fatal issue. When the writer himself began practice, chloroform was just coming into use, and he was anxious to make use of it in puerperal eclampsia. In a case seen with his father a convulsion had occurred, and consent was given reluctantly to make trial of the anæsthetic. This was done, but the convulsions were not averted, the patient grew worse and worse, until finally phlebotomy was insisted on. Thirty ounces of blood were removed, the convulsions did not again recur, and the patient recovered. The author related a number of cases occurring in his own practice in later years in which chloroform, chloral, the bromides, and opium were used persistently, but the patients continued to grow worse; but when, finally, venesection was with many misgivings resorted to, improvement at once took place, and the lives of the women were saved. In every case cathartics were given early, and the uterus was emptied of its contents as speedily as possible, yet no favorable change occurred until the blood-letting had been practised. Irregularity of the pulse was insisted upon as an imperative indication for the abstraction of blood. The author had never seen a fatal case either in his father's practice or in his own when venesection was practised, and he asserted that if this measure was resorted to before consciousness had been abolished the patient would not die of eclampsia. The lancet was the sheet-anchor in convulsions of pregnant and parturient women. The author laid down the following rules, which should be followed in every case of pregnancy: 1, Always see the patient at least two months before the completion of her term; 2, test the urine frequently; 3, if there is much persistent headache, open a vein and bleed until the headache is relieved; 4, warn the patient against indulging in an improper diet; 5, keep the bowels open; and 6, if the patient be seen for the first time at the beginning of labor, and convulsions are threatening, resort at once to venesection.

Dr. Moore, of Monroe County, had had a somewhat less happy experience than the author of the paper, and he had seen cases that did not yield to blood-letting. He believed that the only real cure was to be obtained by eliminating from the blood the poison that occasioned the convulsions, and the way to do this was to produce abundant catharsis. He preferred for this purpose the saline cathartics. But the action of cathartics is not instantaneous, and in order to gain time it is necessary to avert the threatened convulsion by some ready means. Blood-letting will do this; but ether, not chloroform, will also do this and do it better. He always gave ether, in puerperal convulsions even, and especially, when there was unconsciousness with stertorous breathing. He gave plenty of it, and kept the patient profoundly under its influence, for hours if necessary, until the cathartic had produced a copious evacuation of the bowels.

Dr. Pomeroy, of Monroe County, related a case in which convulsions occurred again and again, in spite of the use of chloroform, and did not cease until the bowels had acted thoroughly. He thought the lancet was useful in certain cases, but the thing of prime necessity was free catharsis.

Dr. Hovey maintained that the main thing to do in a case of puerperal eclampsia was to empty the uterus.

Dr. Thayer, of Kings County, agreed with Dr. Moore as to the value of ether, but preferred veratrum viride. The treatment of convulsions by means of this agent was very extensively practised in Brooklyn, but the doses, to be effectual, must be large—a drachm of the tincture. This drug reduces the rapidity of the circulation speedily and permanently, and when the pulse is lowered the convulsions will cease. Drachm doses may be repeated every hour, according to the indications afforded by the pulse.

Dr. Cronin, of Erie County, mentioned the former division of eclampsia into apoplectic, epileptic, and hysterical. It is in the epileptic form that bleeding is useful.

In closing the discussion, Dr. Colvin insisted again upon the irregularity of the pulse as an indication for phlebotomy. When this irregularity occurred, he maintained, death was near, and nothing could ward it off but blood-letting.

A paper by Dr. B. L. Hovey, of Monroe County, on "The Practice of Medicine Forty Years Ago, with Comparative Position at Present," was read by title.

Dr. C. C. F. Gay, of Erie County, then read a paper on

fracture of the base of the acetabulum.

It has been said that this fracture rarely occurs, and that when it does, it is due to a violent injury over the trochanter. But the object of the present paper was to show that it is of not so infrequent occurrence, and that it may be produced by comparatively slight causes. There may be a simple straight fracture, or the base of the acetabulum may be shattered and broken up along the lines of union of the original bones. The fracture may occur alone, or may be complicated with a fracture of the

innominate bone, and the head of the femur may or may not be displaced. It may occur at any age. The author related a case seen by him in which the patient had fallen sixteen feet, striking on the right hip. Upon examination, under ether, there was found a slight eversion of the foot, with no shortening, and it was stated that crepitus was present. Extension of a few pounds' weight was applied and afforded relief to the severe pain complained of. The following day another examination was made, and the same signs observed, except that no crepitus could be obtained. Some days later the limb was again examined. Soon after, symptoms of septicæmia presented themselves, and the patient died. At the autopsy the joint was found filled with pus, which had found exit into the abdominal cavity. The base of the acetabulum was fractured in three directions, following the original lines of union of the bones. The only prominent symptom in fracture of the base of the acetabulum is severe and persistent pain, increased by movement or by pressure against the trochanter; there is no shortening, no deformity, and no crepitus. This accident, when there is no displacement of the head of the femur, is not fatal, nor even dangerous, provided the patient be let alone. It is the frequent manipulation and examination that causes the change. The management of a case of fracture of the base of the acetabulum consists simply in giving perfect rest to the joint. When fracture is suspected, the patient should be kept in bed with the limb resting in an easy position, and extension may be made or not according to the amount of relief which it affords to the patient.

There was no discussion of this paper, but several of the members thanked the author for his communication, as having indicated to them the correct diagnosis in several perplexing cases which they had under treatment at the present time.

Dr. J. G. Orton, of Broome County, then related

A CASE OF TUBAL PREGNANCY, AT FULL TERM, OF FOURTEEN YEARS' STANDING.

The patient had passed through what seemed to be a normal pregnancy, at the expiration of which some abortive attempts at delivery were made. These subsided in a little while, and as time went on and no further symptoms were developed the conclusion was arrived at that a mistake in diagnosis had been made. The patient's health declined, and for eighteen months she was very ill; but at the end of this time she began to improve, menstruation returned, and she was soon perfectly restored. The tumor remained, however, and fourteen years later she began to have a considerable fluid discharge. On examination an opening was found in the rectal wall, through which a hard and movable body was felt. A bullet forceps was introduced, and brought away the femur of a full-grown fœtus. In numerous subsequent sittings, held about every second day, about one hundred bones were removed. The patient was then attacked with a diarrhœa prevalent at the time, and died. At the autopsy the right Fallopian tube was found greatly enlarged, and on opening the sac the remaining bones of a full-term fœtus were found.

Dr. Nathan Bozeman, of New York County, then presented a communication on

TWO CASES OF EXTRA UTERINE PREGNANCY, CONSIDERED IN RELATION TO DIAGNOSIS AND TREATMENT.

The first case was one of rupture of the tube, with profuse hemorrhage into the abdominal cavity. Laparotomy was performed, but the patient died thirty-three hours after the operation. The second case was one in which abdominal pregnancy had occurred, but gave rise to no more dangerous symptoms than a very severe pain in the abdomen, which was controlled by morphine. The patient continued for three years in excellent health, except that she suffered from violent facial neuralgia. At this time menstruation ceased, and the woman was found on examination to be again pregnant. She was taken with pains, and was delivered of a seven-and-a-half months' still-born fœtus. At the time of delivery a hard body was felt presenting in Douglas' *cul-de sac*. An incision was made, and the bones of a dead fœtus, almost entirely deprived of the soft parts, were removed. The patient made an excellent recovery, and is now perfectly well.

The credit of being the first to insist upon early laparotomy in the case of rupture of a tubal pregnancy belongs, the speaker said, to the late Dr. Stephen Rogers, of New York. Since then, the successful results obtained by Mr. Lawson Tait have placed this operation in the foremost rank of availability. The treatment of tubal pregnancy in the early months consists in the destruction of the fœtus by electricity. In this way we are able to avoid the graver operation of laparotomy which becomes imperative upon rupture of the tube.

Dr. Arnold, of Albany County, stated that there was a specimen in the Albany museum of a tubal pregnancy in which the fœtus had been carried for fifty-two years.

Dr. Newman, of New York County, related a case of delivery of the bones of a fœtus through the rectum very similar to that reported by Dr. Orton. The speaker approved of electricity in the early stages.

Dr. Bozeman, in concluding, related a case of tubal pregnancy, with threatened rupture, now under treatment by electricity. An interrupted galvanic current from fourteen cells is used, the negative electrode being passed up by the side of the uterus with the positive pole on the abdomen. One or two applications are supposed to be sufficient to cause the death of the foetus, but four are generally made to ensure success.

Dr. C. S. Bull, of New York County then read a paper on

HYDROCHLORATE OF COCAINE AS A LOCAL ANÆSTHETIC IN OPHTHALMIC SURGERY.

The first knowledge which we had received of this new application of the alkaloid of coca, was obtained, the speaker said, through a letter of Dr. Noyes published in The Medical Record. The author gave the results of a number of experiments made with this substance. In one hundred and fifty cases he had obtained complete anæsthesia of the conjunctiva in all but three. The mydriatic effects of cocaine are less marked than those of atropine. Dilatation of the pupil occurs more slowly and recedes more rapidly than when the latter agent is used. As regards accommodation, the range is shortened and the near point recedes. Recession of the near point begins within twenty minutes after instillation of the four per cent. solution, increases during fifteen or twenty minutes, and then diminishes. Complete paralysis of accommodation was never observed. The effects of the alkaloid as an anæsthetic are chiefly superficial, though the deeper structures are slowly affected. Anæsthesia of these parts, however, can be obtained by injection of the solution into the anterior chamber. The author related a number of cases of operation upon the eye in which no pain was experienced. He believed that every operation in ophthalmology, with the possible exception of enucleation of the eyeball, might now be painlessly performed, and he predicted that ophthalmologists would in the near future be released from the thraldom of ether. By means of this anæsthetic also paracentesis of the drum membrane could be performed without pain. It was also of value in acute nasal catarrh. By an application, by means of a probe armed with cotton, to the mucous membrane of the anterior and posterior nares an acute coryza could be cured. After such an application in his own case the respiration became perfectly free, and remained so for five hours: a second application then completed the cure.

Dr. Mitchell, of Rensselaer County, desired to add his testimony to all that had been said of the value of cocaine hydrochlorate. He had used bromide of ethyl very largely in ophthalmic practice, and considered it of

great value. Prompt effects were obtained in one or two minutes and the recovery is almost as speedy, and it was, he thought, absolutely safe in short operations. But this new anæsthetic agent seemed destined to supersede all others. He thought it especially useful for diagnostic purposes in the case of young children, as even the most timid would allow the eye to be handled without shrinking when they found that manipulation caused no sensation.

Dr. Squibb, of Kings County, said that he had received over three hundred letters asking for cocaine immediately after the publication of Dr. Noyes' letter in The Medical Record. He had tried to extract the alkaloid from coca leaves; but had as yet succeeded in obtaining only about enough to show that it really was the hydrochlorate of cocaine. The price of the drug was formerly $2.50 per gramme (15 grains), but was now about fifty cents a grain, and was likely to be more expensive before it became cheaper.

Dr. Frederick W. Putnam, of Broome County, read a paper entitled

A REPORT OF A CASE OF DISLOCATION OF THE FIRST PHALANX OF THE THUMB FORWARD.

Few such cases have ever been reported. In the case cited, a boy ten years of age fell from a swing, dislocating the first phalanx of his thumb forward. There was severe pain but very little swelling. The luxation was readily reduced, and the case did well. (The original report of this case appeared in vol. xxv. of The Medical Record.)

Dr. Jonathan Kneeland, of Onondaga County, had his paper on "Common-Sense *vs.* Hypothetical Medication in Treating Chronic Diseases," read by title.

Dr. John P. Gray, of Oneida County, next read his paper entitled

INSANITY—PREVENTIVE MEASURES.

The idea of his paper was to give a few hints on the prevention of insanity. Modern science has suggested health boards which are authorized to proclaim the laws of hygiene and enforce them. In contagious diseases persons can even be removed from their homes and isolated. Compulsory vaccination is the extremest step that has been taken in this direction. In ordinary diseases, however, the individual is left to his own discretion. Insanity is a disease of frequent occurrence, and to a great extent within legal control. This is a necessity to protect the public as well as the patient. Over twelve thousand persons are confined in asylums in New York State. Medical men have a great responsibility in this matter, as only they can commit to asylums.

CAN ANYTHING BE DONE BY GENERAL PRACTITIONERS TO PREVENT THE BEGINNING OF INSANITY?

The habits of body and mind, emotions, disposition, etc., must all be carefully considered. Insanity means sickness of body producing sickness of mind. The average medical man thinks of insanity as the last thing liable to happen. Physicians in large practice often say they see very little of insanity. The reason of this is probably that persons having a family physician are less liable to suffer from severe depreciation in health, which leads to insanity. An early recognition of a *flagging of the nervous system* is of the first importance. *Rest and food* are then of greater importance than travel. Sedatives and narcotics disorder nutrition, and do more harm than good; if they are much used, the patient is apt to go from hypochondriasis to melancholia, often ending in suicide. Chalybeates, milk, and malt, and nourishing food, do better than sedatives.

CHILDREN AND YOUTH ARE SENT TO SCHOOL TOO SOON AFTER RECOVERING FROM DISEASES LIKE SCARLATINA AND MEASLES.

They are thus apt to contract such affections as hysteria and chorea. An early recognition of *changes in the character* is of the greatest importance. An unnatural timidity or anxiety are among the earliest changes. Patients must be taught to resist such tendency, and their nourishment be increased in every way. They must be treated as sick persons when in this uncertain mental state, due to disordered health. At the same time the patient's apprehensions should not be aroused—loss of sleep and too little food generally precede such a state. The early stages of alteration in health and character can be often best recognized and overcome by the family physician.

Evening Session.

Dr. Gross, of Philadelphia, being present, was invited to sit as a delegate.

Dr. Stephen Smith, of New York, submitted the conclusions of a paper on

EXCISION OF THE KNEE IN PREFERENCE TO AMPUTATION IN CERTAIN DEFORMITIES OF THE LEG.

The class of cases referred to were described as flexions of the leg due to chronic disease of the joint, or from other causes, which prevented the limb from being straightened so as to bring any part of the foot to the ground. In these cases the joint is not always seriously compromised, but the long-continued flexion has led to such a contracture of parts that it is impossible to put the limb in a useful position without excision. The operation gives much *better results as regards future usefulness* of the limb than amputation.

Dr. Gross, of Philadelphia, described an operation devised by his father, by which the partial anchylosis of the knee may be overcome.

Dr. E. M. Moore, of Rochester approved of excision in the class of cases referred to in the paper.

Dr. George Harrison, of New York, read a paper on

THE CURETTE, ITS PLACE AND ITS POWER IN UTERINE THERAPEUTICS.

Two problems presented themselves as to its use. First, to determine what conditions demand its use, and second, the best method of using it. It was very useful in removing morbid, soft structures from the inner surface of the uterus.

A paper on

THE RELATIONS BETWEEN TUBERCULOSIS, JOINT DISEASE, AND GENERAL TUBERCULOSIS,

was read by Dr. Dennis, of New York.

Recent pathological researches have shown that joint disease are primarily generally due to tuberculosis and very rarely to traumatism. Clinical facts show that a close relation exists between acute miliary tuberculosis and local tuberculosis. Tuberculosis starts from a focus, and this focus is a diseased lymphatic gland. The central cheesy foci situated in diseased glands afford means for the development of the disease. He then gave the history of a case in which a cheesy mass was taken from a diseased wrist-joint, and the microscope showed it to contain bacilli tuberculosis. The patient some weeks after died of acute miliary tuberculosis. This is the most important link showing the relation between the two affections. Acute miliary tuberculosis is an infectious disease, and may be developed by inoculation or by inhaling tuberculous material. The removal of the cheesy glands which contain the foci of the disease is the easiest means of eradicating it. Marked improvement in cases will generally follow the removal of the cheesy masses. Examine the character of the discharges in every case to determine the presence of bacilli of tuberculosis. The greatest danger from tubercular joints is acute miliary tuberculosis.

Dr. Gross said primary articular tuberculosis was identical with tuberculosis of testicle and other parts of the body, and this connection was shown in the cause of death. He advocated the opening of the joint and removal of diseased tissue and then sprinkling the parts with iodoform.

Dr. Dennis then presented some specimens of the disease.

Dr. W. T. Lusk read a paper on

THE MANAGEMENT OF BREECH CASES IN WHICH BOTH LOWER EXTREMITIES ARE BENT UP PARALLEL TO THE ANTERIOR SURFACE OF THE CHILD.

In these cases Nature most often fails to finish her work. Emergencies rarely arise before the breech has descended into the brim. Many object to the use of instruments in these cases, but experience recommends their use in cases where manual manipulation is of no avail. The chief objection to the forceps is that it is designed to take only the head. If applied to the breech it may slip off or break the pelvic bones, lacerate the soft parts, or kill the child, sometimes injuring the soft parts of the mother. Since the introduction of the traction-forceps a new impulse has been given to the use of forceps. The use of forceps is inadmissible unless the breech does not engage the brim of the pelvis. The extraction of the child must not be made an exhibition of strength. But little force is needed. Traction force is most successfully used during the pains. If the forceps fails from any cause, or is inadmissible, the employment of the fillet is admissible. Dorso-posterior position calls for especial caution when traction is made from the groin. The main drawback to the use of the fillet is the difficulty of passing it around the thigh in most of those cases in which it is most useful. The objection to the blunt hook is due not to inherent defects in the instrument, but to want of care in its use.

Dr. Thomas H. Manley read a paper on

WOMEN AS MIDWIVES,

in which he advocated their employment among the working classes, and the opening of *schools for their education.*

Thursday, November 20th—Third Day—Morning Session.

The Association was called to order at 9.30 A.M.

A preamble and resolutions on the death of Dr. John G. Adams were offered by Dr. Purple and adopted by the Association.

DR. GOULEY THEN ASKED EVERY MEMBER OF THE ASSOCIATION TO FURNISH HIM WITH THEIR PICTURE.

Cards containing an order on a photographer would be furnished them, and he only wished to have one picture left for himself. He already had their autographs and he wished to remember them all personally.

Dr. Flint, Sr., then offered resolutions thanking Messrs. Carnegie and Vanderbilt for their recent munificent gifts to the cause of medical science. Unanimously carried.

The committee on nominations reported the following

OFFICERS FOR THE ENSUING YEAR:

President—Dr. John P. Gray, of Oneida County.

Vice-Presidents—Second District, Dr. W. H. Robb, of Montgomery County; Third District, Dr. J. G. Orton, of Broome County; Fourth District, Dr. Joseph O. Greene, of Erie County; Fifth District, Dr. J. C. Hutchinson, of Kings County.

New Members of Council—First District, Dr. William Gillis, of Franklin County; Second District, Dr. R. C. McEwen, of Saratoga County; Third District, Dr. Frederick Hyde, of Cortland County; Fourth District, Dr. Darwin Colvin, of Wayne County; Fifth District, Dr. J. W. S. Gouley, of New York County.

Report unanimously adopted by the Association.

Dr. Austin Flint then delivered an

ADDRESS ON MEDICINAL AND NON-MEDICINAL THERAPEUTICS.

The scope of his remarks was to define the term therapeutics, which may denote drugs only, or, in a broader sense, any means or appliances for the cure of disease. It is popularly considered to be the chief business of physicians to use drugs. The prevailing sentiment at present is that a doctor without drugs is like the play of "Hamlet" without *Hamlet.* A case was cited in which a patient who had recovered from pneumonia without the use of drugs complained of the inattention of the physician. Professional visits without a prescription are often deemed useless by the patient. In the popular sense, *medicine* means drugging. A knowledge of anatomy and physiology are not appreciated by the public. A physician should not be considered only as a dispenser of drugs. It often takes better judgment to *withhold drugs* than to give them. Nothing is easier than to give drugs. The time will come when the doctor will be considered a *medical counsellor,* and this reformation must take place in the public mind. Nature is always the efficient curative agent, and most diseases tend by themselves to recovery. It is to this fact that irregular systems of medicine owe their popularity, especially in regard to infinitesimal doses. There is considerable diversity of opinion among physicians as to the effects of drugs; some are too confident of their powers, and others too sceptical.

There are *pharmacomaniacal* doctors as well as patients. Each new remedy is eagerly accepted and the old one discarded. The *sceptical* doctor shows the reverse picture, and the truth lies somewhere between these extremes. We must be satisfied that potential drugs are clearly indicated before using them. Clinical experience is the only rational ground upon which drugs are to be used, and hence the importance of close observation. The results of experiments on lower animals must be accepted with caution. It was empiric knowledge that first led to the use of such drugs as cinchona and mercury, although now we think they may act as parasiticides. Theoretical knowledge has rarely been of much clinical use. The parasitic idea of the etiology of disease offers a great future for therapeutics in the line of discovery of parasiticides. Non-medicinal therapeutics are not much appreciated by the pharmacomaniac. Harm may be done by the use of non-medicinal agencies as well as by an injurious use of drugs. Diet is an essential factor in therapeutics, and we must keep in view that there is never danger from over-nutrition. The lethal agency in exhausting diseases is always denutrition and starvation. If patients can digest and assimilate food they cannot be overfed. The best principles of therapeutics are in accord with *common sense.* There must be a regard for nature's wants, and appetite and taste generally show what is needed. In cases like the essential fevers, where the appetite is gone, reliance must be placed on milk and eggs. With regard to beef-tea, extracts, etc., the nutriment is almost *nil,* although they act as stimulants to the digestive fluids. Beef-tea has been compared to urine. Leube's solution contains the equivalent of solid flesh, and Rosenthal has made it more palatable. Most nervous diseases are due to deficient nutrition. Is alcohol a food? To a certain extent it is, inasmuch as it is not expelled from the body as alcohol. It should not be withheld in disease, even if it is not always desirable in health; the tendency of late years has been to use alcohol rather more restrictedly.

In certain cases of phthisis, alcohol retards the disease and it sustains life in typhoid fever. It prevents tissue waste and has antiseptic properties. The term to *catch cold* is indefinite and does harm among the laity. Sick rooms are poorly ventilated, and sponging deemed hazardous; in pneumonia, especially, is there a popular prejudice against cold. Few diseases are due directly to cold, and a fever patient never catches cold. The mental influence of the doctor on the patient is important. Some never succeed because they cannot inspire *confidence, faith, and hope.* One class of physicians are too sanguine, and thus err in prognosis; another class are too pessimistic. A gloomy prognosis may contribute to its fulfilment. *Faith cures* show the influence of the mind on the body, and physicians may learn something from them. The introduction of the term *neurasthenia*

has done harm. Too much introspection must be avoided, and the sanitary effects of work not overlooked.

Resolutions of sympathy with Dr. Sayre in his illness were carried.

RESOLUTIONS OF THANKS TO DR. J. W. S. GOULEY FOR THE ENERGY DISPLAYED BY HIM IN CONNECTION WITH THE ASSOCIATION

were also carried.

Dr. John P. Gray, the President-elect, then took the Chair. He made a brief speech in which he stated that the Association was not an offshoot, and represented neither new code, old code, nor no code, but was intended to keep up the fellowship and feeling that had formerly existed in the profession.

Afternoon Session.

The first paper read was by Dr. Gaspar Griswold, of New York County, on

FALSE ALBUMINURIA.

There were two classes of cases considered by the speaker: 1. Those in which the urine does not contain albumen, but in which a precipitate resembling albumen is thrown down by the ordinary tests. 2. Cases in which the urine does contain albumen, but this albumen is not excreted by the kidneys, and consequently is not a sign of nephritis. The author described the methods used by himself in order to discriminate between different precipitates, and concluded by insisting upon the necessity of correct methods in testing the urine for albumen.

Dr. Samuel W. Smith, of New York County, then presented a communication entitled

THE EARLY USE OF THE KNIFE IN NÆVUS OF THE CAVERNOUS ANGIOMA VARIETY AS CONTRASTED WITH OTHER MODES OF OPERATION FOR REMOVAL.

The author urged an early operation by the knife, because of the rapid growth of the tumors, and reported two cases in support of his preference.

The following papers were

READ BY TITLE

and referred to the Committee on Publication.

"Stretching of the Nasal and Infra orbital Nerves in Ciliary Neuralgia," by Dr. C. G. Ross, of Chemung County; a case of "Ovarian Cyst with Operation," by Dr. T. M. Lloyd; "Organic Disease of the Brain not a Constant Factor in Insanity," by Dr. Simeon T. Clark, of Niagara County; "Supporting the Perineum in the Act of Parturition," by Dr. Jacob Hardtman, of New York County; "Report of a Case of Gunshot Wound of the Stomach, Recovery," by Dr. John H. Hinton, of New York County.

Dr. E. G. Janeway, of New York County, next read a paper on

ABSCESS OF THE LIVER.

The doctor has seen a comparatively large number of cases of abscess of the liver during the past year, and thinks that the disease is not so infrequent in this climate as is usually supposed. The abscess may be single or multiple. The idiopathic form is to be distinguished from that ocurring when there is infection through the portal circulation. Sometimes several small infective abscesses may coalesce and form a single abscess, resembling the idiopathic form. During the present year the doctor has met seven cases; of these three died and four recovered. Of those that recovered, in three cases the abscess was opened by operation and one opened spontaneously.

Dr. J. Lewis Smith, of New York County, then read a paper on

DIPHTHERITIC CROUP.

He stated that croup was usually, but not always, a local manifestation of diphtheria. Any severe inflammation of the larynx might result in the formation of a pseudo-membrane. He related a case of membranous croup in a child, twenty-five months of age, due to "catching cold." Croup did not occur always from propagation of the specific inflammation from the pharynx and fauces, but might be the first manifestation of the disease. It might also occur in the course of diphtheria, notwithstanding the most thorough disinfection of the faucial exudation. Whenever in a case of diphtheria the patient became hoarse or presented any other signs of implication of the larynx, treatment by inhalations of lime-water was imperative. When any marked dyspnœa was present, not more than one in eight patients could be saved without tracheotomy. The room should be filled with steam from a croup-kettle or atomizer; to the lime-water in the atomizer liquor potassæ, in the proportion of one and a half per cent., being added.

Dr. Rochester, of Erie County, related a case in which he employed a mixture of iodoform and bismuth (one part to two) in insufflation; no other treatment was given except stimulation.

Dr. Reese, of Kings County, since he had used kerosene in inhalation, had never had a fatal case of croup.

Dr. Moore, of Monroe County, had found frequent insufflations of bicarbonate of soda most effectual for dissolving membrane.

Dr. Austin Flint, Jr., related

SOME TYPICAL CASES OF DIABETES MELLITUS NOT BEFORE REPORTED.

They illustrated the value of arsenite of bromine (three to five drops of Clemens' solution three times a day) in conjunction with a rigid anti-diabetic regimen. In conclusion he quoted a statement of Cantani that diabetes was readily curable provided only that treatment be begun in an early stage.

Dr. Clark, of Vermont, said that in his own case he suffered greatly from dyspepsia when starchy foods were excluded. He found sugar in his urine when the specific gravity was reduced to 1.003.

Dr. Fifiene, of Boston, related the case of his son, who suffered from diabetes after the bite of a bull-dog. He did not believe that dieting would ever cure diabetes in the young, and if it did in the old it must be because of some constitutional difference.

Dr. T. W. Ross, of Chemung County, reported a case of

RUPTURE OF THE UTERUS,

occurring in a woman with narrow pelvis, who had had nine previous pregnancies, none of them, however, going to term.

Dr. Bontecou, of Rensselaer County, then exhibited a patient illustrating

A CASE OF CONSERVATIVE SURGERY AND ITS RESULTS.

The patient was shot in the late war and suffered a very extensive injury of the shoulder-joint. Exsection was performed some month later, as much of the periosteum having been saved as possible. There had been a considerable reproduction of the shaft of the humerus.

A paper was then read by Dr. J. W. S. Gouley, of New York County, entitled "Report of a Case of Ligature of the Primitive Iliac Artery for Diffuse Aneurism of the External Iliac Artery."

The session was then adjourned.

At the close of the session on the third day two hundred and thirty-eight members had registered.

The Fellows residing in New York County entertained the Association at supper in the evening at the Murray Hill Hotel.

The programme for Friday included surgical operations at Bellevue Hospital at 10 A. M., an exhibition of various bacilli at 11 A. M., and an excursion to the hospitals on Blackwell's, Ward's, and Randall's Islands at noon.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHANGES IN THE ARMY MEDICAL DEPARTMENT—EXAMINATION FOR PROMOTION—ANOTHER MEDICAL JOURNAL—VICTORIA AND LONDON UNIVERSITIES—MEDICAL DEGREES—CRISIS IN THE LONDON MEDICAL SCHOOLS—PROPOSED UNION OF THE TWO LONDON COLLEGES—REFORM OF THE COLLEGE OF SURGEONS—SIR LYON PLAYFAIR AND MEDICAL REFORM.

LONDON, November 1, 1884.

CONSIDERABLE changes are being effected in the Army Medical Department, and some of them are giving rise to disaffection, if not hostility. First of all the Department is to be furnished with a brand new name—"The Medical Staff." This is not sufficiently dignified for some, who think it entitled at least to the prefix "Royal," which has indeed been recommended by two important committees of inquiry; but for some reason, comprehensible perhaps to the official mind, has been withheld. It is said, however, that it may even yet be conferred. I do not know that it will do our army surgeons much good, but if they desire an empty distinction of the kind, their arduous services entitle them to the honor.

Army surgeons have a further grievance: honors and distinctions are conferred freely enough on combatant officers, even when they have run no particular risks, but are only grudgingly awarded in the fewest possible cases to surgeons whose lives have been freely exposed in the performance of their duty. It is a curious thing to observe that the name of the head of the Medical Department appears in the army list without any military decoration. There has always been a jealousy between combatant and non-combatant officers. The former have affected to look down upon their surgeons, except of course at the time their services were in actual demand.

Another important change is also to be inaugurated. An examination for promotion to the rank of Brigade-Surgeon is to be instituted; and the feeling with which this regulation is received by those who will have to be examined is naturally the reverse of pleasant. The Duke of Cambridge stated before a parliamentary committee that to "examine a man up to fifty years of age is hardly fair, and that if the heads of the department do their duty they ought to judge of the fitness for promotion of medical officers without examination." Speaking as a civilian I should think His Royal Highness must be right. There are some people who think examination can test everything. It would open their eyes if they were examined themselves. One defender of the new proposal says that a good administrative officer requires tact as well as temper. Fancy examining a man to ascertain whether he possesses such qualifications! Another defender asserts that the examination is optional. Of course it is, but passing it will be necessary for promotion; the option, therefore, is of the kind known as "Hobson's choice." I observed some time ago that this question of examination for promotion had been fully discussed in THE RECORD in reference to the regulations of the United States Army. American Army surgeons can therefore sympathize with their British brethren in the infliction to which they are about to be subjected. At first it was actually proposed to examine surgeons-major in operative surgery; but I hear that this rule is to be modified, and further that fellows of one of the Royal Colleges of Surgeons are to be exempted from the new examination.

A new periodical, *The Medical Chronicle*, appeared in October. It may be regarded as the organ of the Manchester Medical School, as it is issued under the authority of an influential committee in that city. But it proposes to give a full abstract of current medical literature. As Manchester is the seat of the new Victoria University and of numerous medical charities, there may be room for such an organ.

Speaking of the "Victoria" reminds me that that university has just missed a great chance of at once becoming one of the most important medical institutions by confining its degrees to the students of its own colleges. Had it thrown open its portals to all qualified practitioners who could pass its examinations, hundreds would have applied for its degree, to whom the condition of residence renders such a distinction inaccessible. But the Victoria does not accept the examinations of other universities, not even of the London, on whose evil model it has so largely framed its regulations.

To other nations it must be almost incomprehensible that the great bulk of English practitioners do not hold a university degree. It is not because they do not desire it, but because the English universities have so framed their regulations as to drive men to the colleges which confer a membership or fellowship, but have no power to grant degrees. That the magic M.D. or M.B. is coveted is proved by the fact that hundreds go abroad to get it, and thousands go to Scotland. Only twenty per cent. of practitioners in England have any connection with the English universities, while nearly sixty-two per cent. hold Scotch degrees. In Scotland itself, ninety-eight per cent. of the practitioners are graduates. You will say that we have a university in London, but that body has devised such a stupid set of regulations that a very small number of students attempt to comply with them, and of those who begin the medical career mapped out for them and pass the earlier medical examinations only ten per cent. obtain the full degree. Was there ever such a specimen of "how not to do it?"

Just now the medical teachers of London are very much concerned about the facts I have named above, and no wonder their best men are leaving them, going off to inferior schools, because the metropolis with its unrivalled facilities for education is unable to crown the edifice with the recognized distinction. The list of entries at the medical schools for the winter session s now completed, and a genuine "eye-opener" it proves to be. The paltry University of Durham with its affiliated school at Newcastle has a larger entry than several of the London schools. Why? Because residence at Newcastle enables the student to take a degree, but residence at London does not. No one can suppose that medicine can be better taught at Newcastle Infirmary than at our great London hospitals; and yet these Newcastle students will soon come out as full-fledged M.B.'s or M.D.'s, with a legal right to call themselves Doctor, while students of Guy's, St. Bartholomew's, St. Thomas', and the London Hospitals, must be contented to style themselves plain Mr., or to append to their names half a dozen or a dozen letters, which are for the most part incomprehensible to the public. I have already informed you that there was a talk of making our two Royal colleges into a university, and this notion has gained ground, until to-day it has obtained the support of *The Lancet*, and many teachers would rejoice to see it accomplished. It ought to be easier with the materials thus to hand to inaugurate a medical university in close connection with the metropolitan schools, than to establish an absolutely new university in all the faculties. Our two colleges have agreed to unite and give a full diploma, which will qualify for practice in every department; but those who take that diploma, though they may be members of both colleges, will still have to call themselves Mr., will still be unable to sign themselves M.D., while their rivals and neighbors who hail from Newcastle or Aberdeen may write Dr. before their names or M.D. after. Unless something is done to remedy this injustice the ruin of the London schools is to be anticipated. In New York, I understand, the College of Physicians and Surgeons confers the degree of M.D. But on

your side of the water you can go ahead and rejoice in your strength; here we are overburdened with our age, and when we attempt to disturb the dust of centuries we are suffocated for our pains.

We have now in working order two Societies for the Promotion of Reform in the London College of Surgeons, and both bodies have put forth their grievances. The Association of *Fellows* have issued a series of recommendations, which are decidedly liberal, so far as they are themselves concerned, and inasmuch as they recognize the existence of *Members;* but they have no notion of making the latter an integral part of the corporation. As the recommendations will be shortly discussed and may be considerably modified, I need not more fully describe them. The Association of *Members* is rather more ambitious, and has actually petitioned the Prime Minister to assign two Members of Parliament to the medical men of the country. I do not suppose the petition will produce more than a faint smile in official circles. No profession, as such, enjoys parliamentary representation, and we may be pretty sure that such an innovation will not be made by a Government of which most of the members are opponents of "fancy franchises."

The mention of Parliament reminds me that the shadow of a coming election is already perceptible in several quarters, and in one is of special interest to our profession. The seat of Sir Lyon Playfair is again threatened; at the last election he was only returned by a small majority. He had deeply offended a large section of his constituents by his action on medical reform, and a medical man was put in opposition; he was, however, again returned for the Universities of Edinburgh and St. Andrews. Since then he has again played fast and loose with medical reform. He has no doubt pleased some of the Scotch corporations, but the majority of his numerous medical constituents are disgusted with his tergiversation, and those who are of the same political party think his time-serving spirit unfit for the representative of an academical constituency. This week, therefore, they have brought forward a candidate, who has promised to contest the seat on the first opportunity. Unfortunately he is a lawyer; and we have too many lawyers in Parliament. He is a thorough-going Conservative, and it is certain that the constituency is rather Liberal than otherwise. Further, though a large part of his address, about half, is taken up with medical politics, he completely misunderstands them, and would be quite as unendurable to medical men as their representative, as Sir Lyon Playfair himself. Only a medical man ought to be M.P. for the Universities of Edinburgh and St. Andrews. It was a mistake when Sir Lyon Playfair, as a Professor of Chemistry, was thought to be a suitable substitute for a *medical* candidate.

COCAINE HYDROCHLORATE IN MINOR SURGERY.

To the Editor of The Medical Record.

Sir: As the subject of cocaine hydrochlorate is somewhat prominent just now, I trust the following case will not be entirely without interest, your editorial of last week being partly responsible for the occurrence. At the semi-annual meeting of the Fairfield County Medical Society, held to-day at the Bridgeport Hospital, one of its members, Dr. Wright, of this city, kindly permitted the following experiment:

The doctor had a small fatty tumor upon his forehead. I passed the needle of an ordinary hypodermic syringe through the skin on one side, and tried to pass it across the tumor between it and the skin, but did not succeed, and so passed it through the tumor. Then while slowly withdrawing it, injected about six minims of a two per cent. solution of cocaine hydrochlorate, obtained from Foucar about three weeks ago. I then rubbed a few minims upon the skin over the tumor with my finger. In five minutes I thrust the needle into the skin over the tumor so as to draw blood. The doctor felt what he described a "sense of pressure," *i.e.*, he knew that I was doing something but felt no pain. In fifteen minutes there was apparently some return of sensibility. I then injected four minims more from the side opposite to that from which the first injection had been made. Dr. Weir, of New York City, who was present with us by invitation, then removed the tumor through a single straight incision about an inch and a half long.

The sensations of Dr. Wright during the operation are given in his own words. No one timed the different steps of the experiment accurately. I give my own estimates above and the doctor gives his below.

"The first injection by the hypodermic needle was quite painful to me, but as it was my first experience in its use upon myself I presume not more painful than to anybody else. In about two minutes I felt a benumbing sensation in and about the tumor, and suggested to Dr. Wilson that it was anæsthetic. He *pricked* it with the needle, but I only felt the *pressure*. In about eight minutes I felt as though sensation was returning to the tumor, but probably I was wrong, for in about ten minutes the second injection was given, of which I felt the initial prick, but was unable to locate from the feeling the place of injection, or the direction in which he ran the needle. In less than five minutes Dr. Weir began the operation, at which time the forehead and face felt anæsthetic for a radius of three or four inches. I felt the first cut through the skin, but it did not seem painful, or, at most, not more so than the scratch of a pin. Then I could feel the blood flowing down my cheek, and hear the grating of the knife, but felt *no pain* at all. I could barely distinguish the prick of the needle when the two stitches were taken. During and subsequent to the operation I felt elated and buoyant, and was less conscious than usual of fatigue during the long exercises of the afternoon, though on my feet the whole time. At no time have I felt sleepy, and though at the present time of writing, about seven hours after the operation, I have scarcely had time to sit down, I do not feel tired, and expect to visit several patients before bed-time. Such excitement and unusual exertion generally gives me a headache, of which now I have not a particle.

J. W. Wright, M.D."

There can be no question that in this single instance the subcutaneous injection of cocaine hydrochlorate transformed a very painful operation into a comparatively painless one. You will notice that Dr. Wright lays most stress upon the pain of the first injection of the drug.

F. M. Wilson, M.D.

317 State Street, Bridgeport, Conn.,
November 11, 1884.

OUR CINCINNATI LETTER.

(From our Special Correspondent.)

CINCINNATI MEDICAL SOCIETIES—COLLEGES—GUNSHOT SURGERY—MIDWIVES.

The medical societies, though baffled through the month of September by the excessive heat, are now down to a working basis, and promise some interesting meetings for the winter. Foremost and oldest of all is the Cincinnati Academy of Medicine. This society has Dr. W. H. Wenning, of St. Mary's Hospital, as President, and George A. Fackler, M.D., as Secretary. It has a large membership and, except on election nights, a fair attendance.

At a recent meeting, Dr. A. Ravogli reported a case of elephantiasis of the leg which he had seen during Dr. Connor's absence. The calf measured three feet four inches in circumference; the whole limb was invaded. Patient was eighteen years of age. The disease had its initial stage in early childhood, which is unusual. The boy weighed three hundred pounds, of which one hundred and eighty pounds were attributed to the leg.

He continued in good health till twenty four hours previous to death. The speaker was inclined to attribute death to an embolus. Said it might have been from pyæmia from excessive lymphangitis. Much interest was taken in this case.

At the meeting next in order, Dr. Hottendorf read an article on "The Abortive Treatment of Typhoid Fever." He reported as occurring in his practice during the last six years twenty-three cases of typhoid fever, fifteen in adults and eight in children. All he treated on the abortive plan, viz., calomel. He gave one-half-gramme doses every day, or more seldom if the case required, during the first week of the disease. He had had most gratifying results, viz., recovery in every case.

The Cincinnati Medical Society is younger, has fewer members, and a lighter attendance than the Academy of Medicine, yet it has some very live men and some very live meetings. The younger members of the profession seem to have a prominent part in its affairs and do the most of the work. While the Faculty of the Medical College of Ohio belong to the Academy, the Faculty of the Miami Medical College belong to the Cincinnati Medical Society. This is the differential diagnosis.

Dr. Dun, at a recent meeting, reported a case of severe shock from electricity—a female clerk of high nervous sensibility. The wires of the electric light became crossed with those of the cash-ball system while she was operating, and she received a terrible shock. She uttered a piercing cry and fell to the floor unconscious. By appropriate treatment she recovered. The doctor said we may expect to see more of this class of cases in the future.

At a more recent meeting Professor W. H. Taylor, one of the physicians on obstetric duty at the Cincinnati Hospital and Professor of Obstetrics at the Miami Medical College, reported the obstetrical department for the last four months he was on duty. He began with a description of the obstetrical wards, which showed very perfect isolation and care. In the after treatment he spoke of a $\frac{1}{2000}$ injection of the bichloride of mercury twice a day for ten days. Pulse and temperature are taken twice a day, and if any patient gives evidence of sepsis she is taken to other quarters at once. During the four months there were 79 deliveries, exclusive of abortions; 42 primiparæ, 37 multiparæ; youngest, 16; oldest, 44. Hyperæmius gravidorum was experienced by 47 in the earlier stages of pregnancy, 32 escaped altogether. Of abnormal presentations there occurred—left occipito-posterior, 1; foot, hand, and cord presented together in one instance. The forceps were used five times and podalic version twice. The reporter continued with an extended temperature chart and brief reports of six cases of difficult labor, two cases of puerperal fever, and one of scarlatina.

Dr. Davy objected to the use of injections in perfectly normal labor, because unnecessary; they disturb the parts, and trouble may ensue from the contact of parts with the hands of attendants and the atmosphere.

Dr. Stanton thought that care in the use of injections would overcome the objections to them. He was in favor of the use of injections, but thought much of the benefit was derived from the water, though the bichloride was not objectionable, and in some cases advantageous.

The Cincinnati Obstetrical Society pursues the even tenor of its way, and is not much known by the general public. It has nearly twenty members, two of whom are of the gentler sex. The members meet monthly at each other's offices or residences.

Our medical colleges are suffering from a decrease in receipts. The number of students has fallen off about thirty per cent. in each. Cause: the requirement of preliminary examination on entering. This has relieved the intestinal tract of the colleges of offending material as promptly as a good cathartic usually acts on the human intestine. Let the good work go on. Despite this decrease in attendance the names enrolled on the lists of private quizzes and private and extra courses has increased, showing a much better class of students than formerly.

The Cincinnati Hospital has been noticeably empty during the past summer. The Hospital of the Good Samaritan has been in much the same condition.

A remarkably interesting case of rodent ulcer occurred at the St. Mary's Hospital in July last. It was of twenty years' standing, in a man sixty-five years of age, and involved the whole right orbit cheek and nose, wanting but three lines of the inner angle of the left eye. Strange to say, after the immense destruction of tissue, the patient appeared in almost perfect health, and was always in good spirits. He left the hospital for his home, of course unimproved. A case of so-called "shaggers" fever, dengue, "break-bone" fever, was one of the curiosities at the same hospital during September last. The patient had been working on the Panama Canal, and brought the disease back with him. He had been sick a year.

The clinics at the Good Samaritan and Cincinnati Hospitals have been very profitable, so far, this term. Our surgeons have been treated with an experience in gunshot injuries recently which they have not seen the equal of since the war. The terrible Court House riots of last March and the election riots of the present month furnished them with about two hundred gunshot injuries. One difference the old surgeons noticed between those made by the militia during the late riot and those made by the soldiers of the late war is that the bullets of the latter day do not stop, but go clear on through. I believe that in no one instance in a wound made by a militiaman's bullet in the riot last March did the ball remain in the person wounded. The day of "probing for the ball" is, it seems, in reality gone by.

Thirty per cent. of the births in Cincinnati are attended by midwives, and yet almost five hundred physicians eke out an existence.

ABRACADABRA.

October 24, 1884.

RECOGNITION OF PRELIMINARY WORK.

To the Editor of The Medical Record.

SIR: In a late issue of THE RECORD, I observe an editorial under the title: "Recognition of Hard Preparatory Work." From time to time criticism of the kind you have made appears now in this medical journal, now in that; now in this form, and now in another. That some complaint is justified by the facts is admitted by all; that the existing evil should receive deserved correcting is the wish of every one. Why, then, does the evil stand, and complaint mock itself? Simply because of the incompetency of the means thus far adopted.

[The writer having discussed the various means heretofore tried and their failure, continues:]

The concluding paragraph of the article referred to above has this also: "Hard preliminary work deserves a little recognition other than the slow and uncertain recompense furnished by the public." Herein is suggested a method of correction which most assuredly will prove competent, because it is based upon the strongest and most constant passion of the human heart—pride. The method is this: Distinguish by some universal insignia or item of dress the graduate in medicine; and also, by modifications of this same, the degree of preparatory education. For instance, let the graduate in medicine be distinguished by some modest decoration, or some suitable device, whatever it may be, to be universally worn and acknowledged. Then, for the doctor of medicine who has been previously graduated in letters with the degree A.B., an additional ribbon or another color added to the M.D., decoration which will secure the deserved recognition; and so on, the degrees B.S., and A.M. and LL.D., etc., may thus receive recognition and

distinguish the "careless and half-educated" from those who have "trained themselves thoroughly." These decorations should be conferred by the same authority and at the same time with the diploma. They should mark no lower course in letters than that of the high school or academy, and the decoration for this course should be the basis or ground upon which the decoration for higher courses, B.S., A.B., A.M., etc., etc., are displayed. Crossing all these decorations for literary training, should be displayed those of professional significance, one for medicine, one for law, one for theology, etc. This scheme will be ridiculed, I know, and chiefly by those who would be made conspicuously deficient thereby. It may also be ridiculed by those of so severe taste as to be offended by anything that in any way distinguishes. It may also be opposed by some as altogether "too silly," etc., etc. However, to the first I would say, your opposition is its very best argument; to the second, it is not at all a question of individual likes and preferences; to the third, what one among you would decline the red ribbon of the Legion of Honor if it were offered?

J. D. KELLY, M.D.

UTICA, N. Y.

PROTRACTED PREGNANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I wish to put on record a protracted pregnancy. The case referred to is Mrs. P——, aged thirty-two; Irish-American; medium-sized. This was her fourth child. The third was born November 24, 1882. She menstruated regularly from the time she began after the birth of her third child until September 22, 1883, on which date the menstrual flow began and continued in the usual manner until September 25th. That was the last time she menstruated until she was delivered of a healthy living child (male) weighing eleven and a half pounds on August 21, 1884, in the evening. The time of parturition was about three hours.

The duration of pregnancy was just three hundred and thirty days. The above dates I can vouch for, for the following reason: The woman was desirous of not having more children, and kept on a calendar the dates of her menstruation, and had not passed her period but a few days before she came to me to see if something could not be done.

The longest case I can find on record is from Leishman's "Midwifery," page 175, where the duration was three hundred and twenty-two days. Professor Atlee records several of one year's duration, I believe, but I never have seen the records myself.

Yours truly,

J. W. WRIGHT, M.D.

THE MORAL EFFECT OF MEDICAL EDUCATION ABROAD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: With regard to the "demoralizing influence" of medical education abroad I must say that, whatever may be the case in the continental cities, the statements made can in no way be applied to the London schools. By no means the least of the advantages of a London education, especially to a young man, is the high moral tone that pervades the profession, and the refining influence that intimate association with men of as high character as the London teachers are, must necessarily impart. I think I can speak without bias on the subject, being a graduate of two prominent universities in this country, and having subsequently passed through the entire curriculum at a London school of medicine. And I venture the assertion that the moral atmosphere of the lecture rooms, dissecting halls, and hospitals in London compare most favorably with any in this country or elsewhere. Any one who has had more than a casual view of the working of a London hospital and of the deportment of its attachés cannot fail to have noticed that the welfare of the patients is the prime object with all concerned, and that in no place is woman held in greater respect or treated with greater delicacy and consideration.

I am, sir, very truly yours,

THOMAS GREAVES, M.D., M.R.C.S., ETC.,

Adjunct Professor of Medicine, Medical College of Virginia.

"CONGENITAL HÆMORRHOIDS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have a curious *lusus naturæ* here in Brooklyn. A baby, female, was born October 22d, of healthy American parents, aged twenty-nine and twenty-four years respectively, being the first child. The mother has always been the picture of health, excepting chronic constipation and its natural result, hæmorrhoids, which have been many years a torment to her, and were naturally extremely aggravated by pregnancy.

At birth the little girl, otherwise well formed, presented, at the verge of the anus, on the right side, a fold of skin projecting three to four millimetres from the normal level of epidermis and five millimetres long by three millimetres broad. This is covered with healthy, normal integument, of natural color and sensibility. It is, then, an *imitation* of a pile, just where the mother's most annoying tumor was located. The little tumor seems to be merely an excess of skin at that point, and is in color and texture so like healthy skin as to show that it cannot be the result of inflammation.

The mother was very anxious to know if her baby "had piles," as she had suffered so much herself, and said "she had been praying for months that her child might be spared an affliction which had caused its mother so much suffering." Is this a *post hoc* or a *propter hoc*?

Certainly the mother directed her thoughts continuously for many days at a time *toward this spot* on her baby.

Is a similar case reported? Yours,

A. B. DE S. SIZER, M.D.

BROOKLYN, N. Y., October 30, 1884.

THE AMERICAN MODE OF GIVING POTASSIUM IODIDE.

TO THE EDITOR OF THE MEDICAL RECORD.

IN your editorial of November 1, in the article headed "American Mode of Using Iodide of Potassium," you state, "The writer also shows that the method originated with the late Dr. Van Buren of this city, and became gradually adopted as the result of practical experience by a number of New York physicians. . . . It is essentially an American, and more essentially a New York idea." I beg to inclose a copy of a prescription I gave in a case of syphilis in July, 1859:

℞. Potassii iodidi ..... ʒ vj.
Ext. sarsæ fluid..... ʒij.
Mucilag. acaciæ..... ʒiv.
M. Two tablespoonfuls four times daily, to be followed by a tumbler of flax-seed tea.

This prescription bears the date (as copied from my note-book) of July 26, 1859.

It will thus be seen that the method of giving iodide of potassium in large doses is by no means a New York method, but was used in New Orleans twenty-five years ago.

As I had only been in this country about five years at that time, it might more correctly be termed an English method. I do not claim any especial credit for giving the remedy in these doses, but, if there be any it should certainly be given to the one who originated it.

J. L. CRAWCOUR, M.D., M.R.C.S., Eng.

194 CAMP STREET,
NEW ORLEANS, LA., November 4, 1884.

P.S.—I would state that the above prescription, with some trifling modifications, was persevered in until

August 11th, when it was given in gradually diminishing doses. The result was an absolute cure, the patient remaining under my observation for twenty years without any recurrence of the disease.

[Many physicians have doubtless given large doses of iodide of potassium. The merit of doing this systematically, of recognizing and teaching it as producing specific therapeutical effects, belongs, so far as we yet can learn, to New York physicians.]

New Instruments.

A CORRECTED DESCRIPTION OF THE CONTINUOUS INDUCTION COIL.

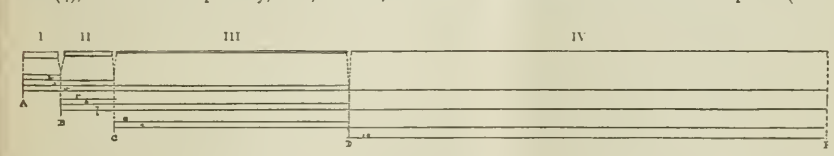
With an Illustration.

By A. D. ROCKWELL, M.D.,

NEW YORK.

The accompanying diagram is here presented and described as it should have been in my article on "The Induction Coil: Its Varieties, and the Differential Indications for their Use," which appeared in this journal, November 8, 1884.

"These coils are, for convenience of illustration, represented by the upper straight lines I, II, III, IV, termed, respectively, the primary, first, second, and third induction coils. The letters A, B, C, D, E represent the different posts of the continuous coil apparatus to which the conducting cords are attached, while the numerals 1, 2, 3, 4, etc., indicate the combinations by which are obtained ten different qualities of current. The short line marked 1, starting from A, represents the current from the short, thick, primary coil marked I. Second line (2), current from the primary and first (I, II) induction coils combined. Third line (3), current from the primary and first and second (I, II, III) induction coils. Fourth line (4), current from primary, first, second, and third



(I, II, III, IV) induction coils. Fifth line (5), current from the first (II) induction coil only. Sixth line (6), current from the first and second (II, III) induction coils. Seventh line (7), current from the first, second, and third (II, III, IV) induction coils. Eighth line (8), current from the second (III) induction coil. Ninth line (9), current from the second and third (III, IV) induction coils combined. Tenth line (10), current from the third (IV) induction coil only."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 9 to November 15, 1884.

Byrne, C. C., Major and Surgeon. Granted four months leave of absence from November 16, 1884. S. O. 265, A. G. O., November 11, 1884.

Tremaine, W. S., Major and Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 233, Department of the East, November 12, 1884.

Wilson, William J., Captain and Assistant Surgeon. Granted leave of absence for four months, with permission to go beyond sea. S. O. 262, A. G. O., Nov. 7, 1884.

Shufeldt, R. W., Captain and Assistant-Surgeon. Assigned to duty as Post-Surgeon at Fort Wingate, N. M. S. O. 217, Department of Missouri, November 4, 1884.

Owen, Jr., William O., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Canby, W. T.' and ordered to Fort Spokane, W. T., for duty. S. O. 169, Department of Colorado, November 4, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending November 15, 1884.

Beardsley, Grove S. Promoted to the grade of Medical Inspector. April 24, 1884. November 14, 1884.

Heffenger, A. C., Passed Assistant Surgeon. Duty at Portsmouth, N. H., continued till December 12, 1885. November 11, 1884.

Opium in Mitral Insufficiency, with an Ethical Episode.—The fact that opium (in small doses) has been frequently recommended of late as a heart tonic, makes the following case, as well as that of Dr. Edson, of especial interest. Dr. George T. McCoy, of Columbus, O., writes that he was called in to see a man, aged sixty-one, who was suffering from congestion of the lungs, with a troublesome cough and severe attacks of dyspnœa at night. Five grains of Dover's powder at night caused an alarming attack of dyspnœa. Dr. McCoy then found that the patient had mitral insufficiency and a dilated heart. Dyspnœa and insomnia continued, and a Dr. L—— was called in consultation. Our correspondent says: "I received a note shortly after Dr. L——'s visit, informing me that that gentleman (?) had assumed charge of the case, and my services were no longer needed. Dr. L—— went to work to 'give his patient rest,' 'he was simply dying for want of rest.' Administered tr. opii, gtt. xxv., every three hours until patient was able to go to sleep. Patient made two attempts to lie down, but the dyspnœa was so aggravated by change of posture that he was fain to be propped up in a chair again. After taking one full dose, and at the third hour half the quantity (in all thirty-five drops) he was enabled to sleep very quietly about four hours, when his breathing became labored, and death ensued without his return to consciousness again. The death was reported by Dr. L—— at the Health Office, as due to 'acute congestion of the lungs." My opinion then, as now, was paralysis of the heart due to opium-poisoning. I am led to make this report by perusing the article of Dr. Edson, in a recent number of The Record, the cases being so nearly

alike in everything except the position of the patient preceding death."

[It is unfortunate that an autopsy was not obtained in order to verify the diagnosis. Not unlikely there was some condition other than those discovered by Dr. McCoy. The best and latest authorities—Bramwell, Allbutt, Sansom, and others—in the continuous dyspnœa, orthopnœa, and insomnia of uncompensated mitral insufficiency.—Ed.]

Accommodation and Presbyopia.—M. Martialis, who is presbyopic, resorts to the following manœuvre when he is without his glasses and wishes to read: He introduces the pulp of the index finger rather deeply between the external border of the orbit and the globe of the eye on that part covered by the upper lid, making somewhat firm pressure. He states that the characters then become visible and he is able to read with ease. M. Martialis thinks that this would be useful in the diagnosis between a simple presbyopia and paralysis of the retina, crystalline opacity, etc. He sees in this a proof of the rôle played by the straight and oblique muscles in the function of accommodation.—*Lyon Médical*, October 5, 1884.

In Dr. Millard's letter, in our issue of November 8th, on the Prevalence of Consumption at Various Ages, page 528, seventh line from the top, 27,771,728 should read: 2,771,728.

The Responsibility of Physicians for Furnishing Proper Certificates of Insanity in cases before them is a matter of great importance, considering the rapidly increasing number of instances where the services of a skilled physician are called for. In a recent case in a New England State the action was brought for damages against a physician for falsely certifying, through malice or negligence, that a person was insane, and thereby accomplishing her commitment to an insane asylum. The pleadings in the suit raised the question as to the actual condition of the person at the time she was declared to be insane, and as the presumption was in favor of the certificate being correct, the burden of proof was upon the persons alleging that she was sane. The court said: "In such an action the falsehood, and not the insufficiency of the certificate, is the ground of action against the certifying physicians. Without statutory provisions to that effect there cannot be a civil action for damages against a physician based upon the insufficiency of the methods which he pursued in reaching and certifying a correct conclusion. In such an action it is open to the defendants to prove precisely what were the circumstances under which they acted, what inquiry, investigation, and examination they made, and what the information was on which they proceeded. If such testimony did not go to the extent of a justification in case their certificates should be found to be false on the question of insanity, it was proper evidence to be considered in awarding damages. If physicians who have certified to the insanity of a person, have not made the inquiry and examination which the statute requires, or if their evidence and certificate in any respect of form or substance is not sufficient to justify a commitment, the municipal officers should not commit, and if they do, it is their fault and not that of the physicians, provided they have stated facts and opinions truly, and have acted with due professional skill and care."

Professional Dignity and What Sometimes Comes of It.—Our London Correspondent sends us the following: "Many doctors are very fond of talking about the dignity of the profession, and how we should all of us do our best to uphold it. An eminent London physician once told me, in conversation, that he makes a point of never thanking his patients for his fee when he takes it, but simply pockets it as a matter of course as his due. I presume he would similarly disdain to ask for it should the patient depart without offering to pay. They sometimes do this. A friend of the writer's who was once treated thus by a lady richly attired, stopped her just as she was making her exit, and in the blandest of terms begged to be allowed to look at the prescription again for a moment. He looked at it for a few seconds, and then, tearing it across, threw it into the fire. 'Ladies in silks and satins,' he said, 'can generally afford to pay,' and calmly rang his bell for his servant to usher in the next patient. Doctors occasionally get the worst of it though, when they stand too much on their dignity with patients. One of the local practitioners in a country town I have frequently visited, was one day sent for to visit a child in the family of one of his patients. On arrival he found his little patient had been ailing for some days, and asked why he had not been called in before. 'Oh,' said the mother, 'we have been giving it a bottle of E——'s stuff,' mentioning a patent medicine prepared by a veterinary surgeon well known in the county, and a bottle of which she had obtained at the chemist's. 'What!' exclaimed the doctor, 'expect me to attend after a horse-doctor?' and he marched off in great indignation. The father of the child was a baker, and supplied the doctor's family with bread. Next day no bread was delivered at the doctor's house. The doctor's wife put on her bonnet and shawl and went out to call on the baker, respecting the omission. On entering the shop she saw the baker's better half, and politely intimated that she had called to say that no bread had been left as usual, and she would be glad to have some sent. 'Oh, no,' was the reply, 'your husband won't attend us as a doctor, so we shan't supply him with bread,' and they didn't. The doctor was forced to deal with another and inferior baker, as similarly the baker had on the previous day been forced to send for another doctor. By the time this appears in your pages medical students and professors alike will be preparing for the opening of the winter session, which is always heralded by the first of October. The Scotch schools do not begin till the first of November. It seems a pity in each case that the studies could not be so arranged as to give more summer holiday, say by beginning in the middle of September and continuing until the first week in July, with only fortnightly vacations at Christmas and Easter, instead of having April as an idle month, and sweltering in town till the last week in July. Some of the medical examinations are even held during August."

The Cost of Sickness.—I think, then, that we cannot escape from the reasons to believe that we lose in England and Wales every year, in consequence of sickness, 20,000,000 weeks' work; or say, as much work as 20,000,000 healthy people would do in a week. The number is not easily grasped by the mind. It is equal to about one-fortieth part of the work done in each year by the whole population between fifteen and sixty-five years old. Or, try to think of it in money. Rather more than half of it is lost by those whom the Registrar-General names the domestic, the agricultural, and the industrial classes. These are more than 7,500,000 in number, and they lose about 11,000,000 weeks; say for easy reckoning, at £1 a week; and here is a loss of £11,000,000 sterling from what should be the annual wealth of the country. For the other classes, who are estimated as losing the other 9,000,000 weeks' work, it would be hard and unfair to make a guess in any known coin; for these include our great merchants, our judges and lawyers, and medical men, our statesmen and chief legislators; they include our poets and writers of all kinds, musicians, painters, and philosophers; and our princes, who certainly do more for the wealth and welfare of the country than can be told in money.—*Sir James Paget.*

Value of Veratrum Viride as a Prophylactic against Peritonitis after Surgical Operations involving the Opening of the Peritoneal Cavity.—Dr. James Roane, of Yankton, Dak., writes: "On August 25th, assisted by Drs. D. F. Etter, and W. H. Turkopp, I operated upon R. S——, a short and spare

Bohemian, aged fifty-five, for the relief of strangulated hernia (right, complete oblique inguinal). A careful and thorough trial of the taxis, at first without the aid of anæsthetics, and subsequently when they were administered to the surgical extent, had failed to produce reduction. Owing to the urgency of the symptoms, the operation was performed at night, and was more protracted than it would otherwise have been on account of the very poor light of a single lamp. The intestine was found to be deeply congested, but showed no signs of disorganization. The constriction was at the internal ring, and its division was followed by the escape of about two ounces of sanguineous serum. The hernia having been reduced, the upper three-fourths of the incision were closed by sutures, and the lower fourth left open for drainage. Throughout its various steps the operation was conducted under strictly antiseptic precautions—a solution of corrosive sublimate, one to two thousand, being used for that purpose. A pledget of absorbent cotton, soaked in this solution, was placed over the wound; this was covered by a larger pad of cotton, and the whole was held securely *in situ* by a few turns of a roller bandage. On coming from under the influence of the anæsthetic the patient vomited stercoraceous matter profusely. He was put to bed, given one-fourth of a grain of morphia hypodermically, and placed upon one minim of Norwood's tincture of veratrum viride, and ten minims of deodorized tincture of opium, every two hours—day and night. This treatment was followed up to the morning of the 28th, when it was discontinued because of the fall of the temperature, the total absence of any of the signs of peritonitis, and the increasing prostration of the patient. The physiological action of the veratrum viride at this time was very marked, manifesting itself in the sense of extreme muscular weakness, and in the slow, moderately full, but soft pulse, which became very rapid on the patient's making the least exertion. At no time after the operation were there any of the local signs of peritonitis, such as pain, tenderness, or tympanitis. The highest temperature (taken under the tongue) was 100.8°; and this occurred on the evening of the 26th. On the 29th the temperature was normal, and subsequently it did not rise above 99°. In that portion of the incision which was closed by means of sutures, union took place by first intention. A slight serous discharge oozed from the lower fourth, left open for drainage for forty hours, but thereafter no stains could be detected on the cotton dressing, and the wound rapidly closed. On September 9th a well-fitting truss was applied, and the patient discharged.

The Modern Iter ad Astra—a Medical Fable.—Once upon a time a poor but humane physician was riding along a road which led by a dark forest, when he saw by the wayside a sick and miserable dog which had lain down to die. Moved with pity he got down from his carriage, picked up the poor animal tenderly, and gave it some food and drink. Suddenly the dog vanished, and he saw standing before him a beautiful fairy.

"You have saved me from a miserable doom by your compassion," she said. "Command now anything you wish, and it shall be yours."

The astonished physician replied, "I am a poor man. I should like to be rich."

The fairy waved her wand, and extended to him a piece of paper and a bottle filled with a dark-colored fluid. "Here," she said, "is a prescription for an Infallible Compound Hair-Restorer. It will never fail, and it has been indorsed by all the leading clergymen on both continents. The world is yours! Do you wish more?"

"I am a quiet man," replied the doctor, "and little known. I should like to be famous."

"You shall be more; you shall be immortal." Waving her wand again, she presented to him a small, dark, and curiously shaped instrument. "See," she exclaimed, "it is a new and 'Unquestionably Perfect Pessary.' It radically restores every malposition. Your name is blown into the side. Generations of suffering women and successful doctors will read, and bless you. I have tried it myself," she added, blushing a little, and vanished.—*Boston Med. and Surg. Journal.*

Renal Calculi and their Removal by Manipulation.—Dr. J. P. Shafer, of Parkersburg, W. Va., sends us the history of a patient, a married lady, thirty-four years of age, who for two years suffered greatly from pains in the back, left iliac region and hip, and retention of urine. This finally culminated in hip-joint disease, an abscess breaking into the vagina, the left limb being shortened one and a half inch. She had also cystitis, and later some hysterical symptoms. In the course of a year she developed violent symptoms of renal colic on the left side. She passed gravel in the urine. Feeling sure that she was passing calculi through the ureters, Dr. Shafer conceived the highly novel plan of helping them along by manipulation. He describes this in the following language: "The patient being placed upon her stomach, so that I could get with my fingers down upon the kidney, by firm pressure, working my fingers, pressing and pulling toward me, I soon found I had changed the seat of pain to another point a little forward, which she could locate by the touch of her finger over the location of the stone, and so I continued this manipulation at intervals, removing each time the stone several inches before stopping to rest again, and each time before again commencing she would locate the point at which the stone was, and so I proceeded until I felt, as well as she, it pass from under my fingers, as I supposed, into the bladder, and which afterward proved to be true. As soon as it passed into the bladder the agonizing pain and muscular spasms ceased at once and the patient became cheerful. She being relieved for the time was happy, and I having performed this feat, the like of which I had never read, heard, nor dreamed of before, of course I was quite well pleased at my success." From this time forward, for the next ten days, she passed calculi every day, the passage being assisted by Dr. Shafer. Then she passed no more for fourteen months, when the attacks began again and continued in the same way and with the same treatment. Dr. Shafer secured some of the calculi, one of which, he says, measures one to one and one-eighth inch in length, by one-half to three-eighths inch in width. He states that he forwards to us some specimens. We have not, however, received them. The patient is still living, and has been seen and manipulated by other physicians. Our correspondent says truly that the case is a very extraordinary one. The fact that the woman is hysterical, suggests the probability of some voluntary or involuntary deception.

Acute Iodism after Three Five-grain Doses of Potassium Iodide.—J. B. Parker, M.D., Surgeon U.S.N., writes: "Extracted from *Journal de Médecine et de Chirurgie Pratiques*, in The Record of the 6th ult., is mention of a case of acute iodism after a single dose of fifteen grains of iodide of potassium. I beg to present the following case, as probably equally severe, after the administration of the same quantity of iodide of potassium in three five-grain doses—morning, noon, and night. Patient, aged forty, a man of superior physique and health, had acute rheumatism in right shoulder. The first evening he came under observation one-sixth grain of morphia sulph. was administered hypodermically, after local dressing with warm laudanum, flannel, cotton, and rubber cloth. Following day patient was given ten grains of bromide of potassium, p. r. n., to relieve pain and induce sleep. This failing to afford the relief desired at night, it was discontinued, and a solution of bromides of potassium and sodium, of each ten grains, and of lithium five grains, was directed to be taken during the day if required, and hourly at night if pain prevented sleep. The succeeding day (fourth) no medicine was taken save three or four doses at night of the bromide mixture, as was

taken during the previous night. The acute symptoms having in great part subsided, he was directed, for the fifth day, five grains of iodide of potassium morning, noon, and night. On the sixth day patient suffered severely from iodism, which he ascribed to *taking cold* during the night, yet was much puzzled to explain its origin, as he had not left his bed and was not aware that a current of air could reach him. When the real cause of his suffering was mentioned he remarked that the remedy was as severe as the disease and preferred not to continue it. The symptoms, which disappeared in twenty-four hours when the medicine was discontinued, were as follows: Pain and constriction in region of frontal sinuses; puffiness and suffusion of eyes, with lachrymation; sneezing and secretion from nose; soreness of jaws and mucous membrane of mouth and throat; ptyalism; cervical glands on left side enlarged and painful; small but painful abscess on helix of left ear, which suppurated and was discharged."

A Breach of Professional Etiquette.—The following story is told of the celebrated Oppolzer. Shortly after his arrival in Vienna he was consulted by an invalid, whom he advised, after a somewhat hasty examination, to go to Pistyan, in Hungary, and take the waters. After several months the man, whom the professor had forgotten, again presented himself, with an aggravation of all his symptoms, and said he had just returned from a course of the Pistyan waters. The professor examined him, this time rather more carefully, and then, with some wrath, asked him what confounded ass had advised him to go there, as it was the worst thing he could possibly have done. Moral: Always speak well of your neighbor.

Whiskey as an Anæsthetic.—In his address as President of the Ninth Annual Session of the Arkansas State Medical Society, Dr. Keller is reported to have spoken as follows on the subject of whiskey as an anæsthetic: "To Dr. Link, of Indiana, are we indebted almost entirely for having gone far toward placing whiskey not only along with ether and chloroform as an anæsthetic, but also in discovering its antiseptic power, equally as safe and effective as any other. So well satisfied is that gentleman from long use of it as his only anæsthetic and antiseptic in amputations, that he asserts he has discarded all others, and in his reports of several hundred cases, he says that he has seen no manifestation of pain during any amputation, no unhealthy action in any stump, and not a single death to mar the report." The manner of anæsthetizing the patient seems to be to administer one or two ounces of whiskey by the mouth every ten minutes "until complete drunkenness is reached," and then, with or without one or two inhalations of ether or chloroform, to proceed to operate. On the face of it, this procedure appears to be open to righteous condemnation. It is well known that acute gastritis may be set up by such means, and the onus of proving that such large imbibitions of alcohol are inoffensive rests with Drs. Link, Keller, and others who may choose to employ the drug. It is possible—anything is possible in medicine—that such treatment may be innocuous; but until more accurate knowledge is forthcoming we prefer to believe to the contrary.—*Lancet.*

Every-Day Physiology.—The weight of a full-grown man should be 154 pounds, distributed as follows: Muscles and their appurtenances, 68 pounds; skeleton, 24 pounds; skin, 10½ pounds; fat, 28 pounds; brains, 3 pounds; thoracic viscera, 3½ pounds; abdominal viscera, 11 pounds; blood which would drain from body, 7 pounds. This man ought to consume per diem: Lean beefsteak, 5,000 grains; bread, 6,000 grains; milk, 7,000 grains; potatoes, 3,000 grains; butter, 600 grains; and water, 22,900 grains. His heart should beat 72 times a minute, and he should breathe 18 times a minute. In 24 hours he would vitiate 1,750 cubic feet of pure air to the extent of one per cent.; a man, therefore, of the weight mentioned ought to have 800 cubic feet of well-ventilated space. He would throw off by the skin 18 ounces of water, 300 grains of solid matter, and 400 grains of carbonic acid every 24 hours, and his total loss during the 24 hours would be 6 pounds of water, and a little above 2 pounds of other matter.

Dogmatic Therapeutics.—The following, from the *Clinical Record*, is an interesting bit of dogmatic teaching, illustrating its attractiveness and its dangers. Item by item it is, if not absolutely incorrect, an expression of half-truth. For chronic constipation, Professor DaCosta has found kneading the bowels to be far more effective than electricity. The best American water for this trouble is Saratoga Congress, but no water should be used continuously. Aloin is the best medicine, and "nothing can be better than a pill of aloin, rheum, belladonna, and capsicum, all in small doses."

Gastric Hysteria and Reflex Uterine Vomiting.—Dr. E. Frank Lyceston propounds four queries upon the above subject. As a general answer we can only say that gastric hysteria and hysterical vomiting may be quite independent of ovarian or uterine irritation.

Shakespeare's Physician.—In the churchyard at Fredericksburg, Va., is a tombstone on which may be deciphered these words:

"Here lies the body of
EDWARD HELDON,
Practitioner in Physics and Chirurgery. Born in Bedfordshire, England, in the year of our Lord 1542. Was contemporary with, and one of the pall-bearers of William Shakespeare, of the Avon. After a brief illness his spirit ascended in the year of our Lord 1618—aged 76."

Increase of Epidemics in Paris.—All epidemics, except scarlet fever, have increased in Paris since 1865. The deaths from measles have increased from 31 to 46 per 100,000; from pertussis, 10 to 19.5; from 43 to 100. Dr. Jacques Bertillon, who gives these facts, thinks that there ought to be a more careful medical supervision of public schools.

Mistakes in Words.—In an editorial criticism upon this subject the *Medical News*, says the *Medical Press and Circular*, "falls into the error, common in republics, of assigning the quality of nobility to the title Sir, since he writes that William Klame, who had been quoted by Siredy as Sir William Klame, is a poor substitute for William Klapp, and it is not compensated for by the title of nobility which precedes it."

An Observation Regarding Menstruation in Animals.—Dr. S. A. Evans, of Conway, N. H., writes: "For several years past I have kept a non-pregnant cow, for the purpose of supplying my family with milk. Have kept a record of periods of heat. Find they recur once in twenty-one days. Are accompanied, first, by a discharge of gelatinous material from vulva, which, after some hours, becomes slightly tinged with blood. The color becomes gradually more pronounced, until within twenty-four hours it appears to be pure blood. Periods last about forty-eight hours. At these periods only can the cow become impregnated, which would seem to show that in her case ovulation and menstruation are simultaneous. These observations have extended through three winters, and in two different animals."

Half a Ton of Serum from the Abdominal Cavity.—Dr. D. Dickinson, Surgeon U. S. N., Mare Island, Cal., sends us the following note: "Nicholas G——, seaman, native of Greece, aged twenty-eight years and two months, was admitted from the Naval Hospital, Yokohama, Japan, on August 18, 1884, and discharged for transportation East, August 31, 1884, as he was anxious to reach Greece before he should die. His hospital ticket stated disease to be dilatatio cordis (et ascites). Within the past seventeen months his abdomen has been aspirated sixty-nine times, withdrawing nine hundred and forty-four pints (nearly half a ton) of serum."

THE APPROACH OF THE CHOLERA AND THE NECESSITY OF BACTERIOSCOPY.

BY EDMUND C. WENDT, M.D.,
NEW YORK.

THE epidemic of cholera which commenced last June at Toulon, has already killed many thousands. It still continues to spread, fortunately, however, with diminished fatality. Nevertheless, the experience of past epidemics should warn us of the possibility—nay, even probability—of its being carried across the ocean to our own shores. Indeed, most authorities confidently anticipate its approach next year. Now, unless we take efficient action in the matter while there is yet time, the dreaded scourge may find us so poorly prepared that widespread disaster must inevitably result.

As has been pointed out by Sanitary Engineer Wingate in a leading daily, published November 23d, "despite the precautions taken by the health officials, no one who is at all familiar with the sanitary condition of New York City can doubt that if the plague once gains an entrance into the metropolis, it will find many nesting places among the dives and slums in certain quarters, whence its baleful influence will spread far and wide. Chief among these hotbeds of disease which constantly invite infection, are the Italian and Hebrew quarters, the former occupying the region of Mulberry, Baxter, and Crosby Streets, and the latter the district in the vicinity of Ludlow, Essex, Hester, and Forsyth Streets." The nuisances on the east side of the city are likewise a source of constant discomfort and serious danger. The same journal has the following editorial comment relative thereto:

"This evil is none the less great because of its long standing. But legal obstacles, red tape, procrastination, or what not, have resulted in the continued exposure of our citizens to the emanations of manure heaps, stagnant drainage, and reeking vats. Here is added cause for Herbert Spencer's wonder at the long-suffering and patience of Americans under imposition. A complaint has been lodged before the State Board of Health, and a heroic band of Beekman Hill women have invaded the pestilential haunts of the malodorous offenders and secured testimony for the consideration of the Grand Jury. These women have pluckily taken in hand duties which devolve upon our Health Department. They have had the courage of their convictions. Where are the courage and the convictions of the officials supposed to care for the sanitary conditions of this city?"

At present "it is more important than ever before that the people of this city should live under the best sanitary conditions. The east side nuisances have been endured too long. They should have been abolished long ago. They must be done away with now."

Such impressive warnings should not go unheeded. And it is quite creditable to our Quarantine Department that it shows renewed vigilance in the matter of preventing contagious diseases from entering our city. Nevertheless, the fact that a fatal case of yellow fever has been quite recently introduced into the city through the failure of the authorities to detect the disease, shows that the medical service of Quarantine is not altogether what it should be. This is still further shown by a resolution adopted at the last meeting of the State Board of Health, held a few days ago, calling the attention of the Governor to the bad condition of the buildings and equipments at Quarantine, and recommending that proper steps be taken for putting them in perfect order.

In the *London Practitioner* for November, 1884, there appears a careful report of the present cholera epidemic in Continental Europe, which shows conclusively that the secret of success in carrying into effect the system of medical inspection and isolation is to be prepared beforehand. And it is impossible to urge too strongly upon local authorities, whether on the coast or inland, the adoption of such an organization and the establishment of such means of isolation as shall enable them to deal with imported infection in its earliest stage.

Dr. Buchanan, F.R.S., in an excellent article on "Precautions against the Infection of Cholera," points out that, it is important for the public very distinctly to remember that pains taken and costs incurred for these purposes cannot in any event be regarded as wasted. The local conditions which would enable cholera, if imported, to spread its infection in any country, are conditions which day by day, in the absence of cholera, create and spread other diseases: diseases which, as being never absent from the country, are in the long run far more destructive than cholera itself. The sanitary improvements which would justify a sense of security against any apprehended importation of cholera would, though cholera should never reappear, give amply remunerative results in the prevention of those other diseases.

The Practitioner says further as having a bearing on this point, "It is also worthy of note that the value of being prepared in advance has been strikingly illustrated during the course of the Italian epidemic. The contrast between Naples and Rome supplies the illustration. In Naples cholera, when once imported, found in the results of centuries of sanitary neglect a soil congenial to its rapid development, and terribly the city has suffered in consequence. But Rome had learned a lesson which even the history of previous epidemics had not impressed on Naples. The Eternal City had provided itself with an abundant and wholesome water supply, and with an efficient system of sewerage, and it had, in addition, adopted other measures calculated to promote the health of its inhabitants; the result being that, although cholera was on five separate occasions imported into the city, no difficulty was experienced, by means of measures of isolation and other sanitary precautions, in preventing any spread of the infection."

It is to be hoped that such positive lessons may not prove barren of practical results. But while physicians and sanitarians are fully alive to the danger before us, they have neglected one point that may be, and probably is, of the highest importance. It is obvious that the earliest possible recognition of the very first case of cholera that might appear among us, would give us the best chance for prompt action to prevent any extension of the disease. Now, it is a lamentable fact that the most careful analysis of symptoms does not always enable us to distinguish, in a given case, cholera morbus from genuine Asiatic cholera. Indeed, it is held by some physicians that the two diseases differ in degree only, and not in kind.

Without stopping to consider this point, we must yet face the fact that our usual methods are inadequate to differentiate with absolute certainty an attack of violent and fatal cholera morbus from one of true cholera. The kind of reasoning hitherto employed by physicians has necessarily been of the *à posteriori* variety. That is to say, if a suspicious case recovered, and was not soon fol-

lowed by other and rapidly fatal cases, the disease was classed as cholera morbus. If, on the other hand, the first suspicious case was quickly followed by an increasing number of fatal cases, the diagnosis of Asiatic cholera was subsequently made. Manifestly, a method of this kind might give the cholera a chance to secure a dangerous foothold before being recognized as such; and one need not be an alarmist to entertain grave apprehensions should such a misfortune befall us. But in view of recent discoveries, it now seems possible to decide positively and in a very short time whether we are dealing with the comparatively benign cholera nostras, or with the eminently malignant Asiatic cholera.

The finding of the specific organism of cholera by Koch was no surprise to those who had long since concluded, without this final and convincing evidence, that cholera must be a parasitic disease caused by a particular and distinct microbe. The grounds on which Koch based his assertion that the comma-bacillus was the causative agent of cholera were, that it was found to be present in all well-marked cases of the disease, and, further, that it was never present in the healthy body or in cases of any other disease.

Koch's conclusions were accepted without hesitation by those who know him best, and who have had occasion to witness his conscientious and painstaking methods of conducting all scientific work. Thus, in Germany, Herr Von Gossler, Minister of Public Worship, Education, and Medical Affairs, has already ordered that a certain number of medical men are to be summoned to Berlin every year to go through a course of study, lasting from a fortnight to three weeks, in order to learn the new methods of investigation connected with bacteria and microorganisms, but chiefly to become acquainted with everything connected with the comma-bacillus and the methods of cultivating it according to Koch's method. The several Federal Governments have been likewise officially requested to select a number of medical men for this course, and to inform them to hold themselves in readiness to come to Berlin. According to the latest Berlin advices these courses are now in active operation, and are very largely attended.

In our own country, however, there is still, even in the ranks of the medical profession, an unfortunate disposition to regard the entire subject of bacteria as trivial or fanciful, and unworthy of serious consideration. There are of course some notable exceptions to this rule. Thus Dr. Austin Flint, Sr., in a recent paper on cholera expressed his unqualified belief in the truth of Koch's assertions. He showed that, wherever cholera appeared the complete destruction of the parasite directly it left the body could be secured, and by this means every case of the disease would be rendered sterile. Koch had proved that the cholera microbe was readily killed by drying, while cold did not destroy its vitality. The local conditions under which the parasite would thrive best outside the body were not yet definitely known, but there could be no doubt whatever that filth was very favorable to its development. Inside the body Koch had shown that the acidity of the gastric fluids was inimical to it. In order that an individual should contract cholera it was probable that there should be a predisposition or susceptibility to it, as was the case in tuberculosis. Hence when we hear it credibly reported that Dr. Klein, of London, a member of the English Cholera Commission now investigating the disease in India, in order to show his disregard for, and lack of faith in, Koch's comma-bacilli, made a meal of them, we can well afford to laugh at such puerile business. Indeed, the *Berliner Klinische Wochenschrift* says: "We had looked for something better from Dr. Klein, and must confess that this so-called auto-experiment gives us no great idea of the discernment and powers of criticism of the abovenamed gentleman." And the *British Medical Journal*, fully appreciating how ridiculous the affair is, states that everybody in London ridicules the experiment.

To-day there seems no longer any possible doubt about the significance of the cholera bacillus. In the *German Medical Weekly* of November 6, 1884, just to hand, Koch has finally disposed of the various objections that had been made against the binding force of his assertions. He has proved by actual scientific demonstrations that the comma-bacillus is the specific micro-organism of genuine Asiatic cholera. The disease has also been artificially produced in animals by the introduction of pure cultures of the parasite in question.

It is not necessary here to reproduce Koch's last article; enough has been said to show that in scientific bacterioscopy we have quite possibly a ready means of detecting with certainty the existence of cholera. But in order to familiarize ourselves with the necessary details of these modern methods, earnest study and some experience are essential. I hold that we have not the right to ignore the light that has been shed on the true nature of infectious diseases by the keenly searching spirit of modern experimental inquiry. In my opinion, it is the duty of our Government to imitate what has been already done abroad. Physicians, or other competent persons, should be sent to Berlin at the expense of individual States, or the Federal Government, to join the classes that have just been organized under Koch's supervision. They should become personally familiar with every step of his painstaking and strictly scientific methods. In a few weeks, or at most months, they could return and be experts and teachers of modern bacteriology.

Should this be found impracticable, however, then let the State Health Boards organize properly equipped laboratories for the purpose of affording suitable facilities for this kind of study and research. Individual physicians with sufficient time and private means should take an active interest in all that relates to the examination and cultivation of bacteria. Is the medical profession of our country to be put to shame by its attitude of apathy toward matters of serious concern to the public welfare? Are we to be made the laughing-stock of our transatlantic confrères? Two well-known physicians of our country have already attempted to overthrow the diagnostic significance of the bacillus of tubercular consumption, the one by claiming it to be a fat-crystal, the other by asserting its identity with shreds of fibrin. But neither the one nor the other had at the time of his pretended discovery ever beheld the true bacillus tuberculosis. To avoid similarly ridiculous errors we need expert teachers of bacterioscopy. This new and highly important branch of medicine should be made an essential and obligatory part of the regular medical curriculum.

That scientific bacteriology is as yet in its infancy all will admit. But let us not blindly ignore its actual accomplishments. We may never be able perhaps to completely eradicate consumption or suppress all contagious diseases, but at present we are without the slightest doubt nearer to such a desirable consummation than we were before the era of bacterioscopy. This is a most important epoch in medicine, and it has been well said by an eminent physician of New York: "It would be to the present era that posterity would look back as the time when those signal discoveries were made which led to the final adoption of the parasitic theory of the origin of all infectious diseases. Was the medical profession in this country to have an active share in this great work of investigation and in these brilliant discoveries, or was it to be content to wait patiently until the announcements of the results of their labors were made by the scientific men of Europe? There was certainly no lack of ability on the part of American medical men, but it seemed to him that there was, at all events, a certain want of self-reliance and energy." If our State authorities are unable or unwilling to help the good work, let the munificence of private citizens proclaim to the world that democracy is at least not inferior to paternal forms of government in producing noble specimens of the *genus homo*.

102 East Fifty-seventh Street, November 25, 1884.

CASES OF STRANGULATED HERNIA, WITH REMARKS ON TREATMENT.[1]

By GEORGE F. SHRADY, A.M., M.D.,

NEW YORK.

During the past few months in my service at St. Francis' Hospital, I have had rather an unusual experience with strangulated hernia, in the number of cases treated within a short period. It rarely happens in the general surgical practice of our hospitals that any surgeon is called upon to operate upon eight cases within a period of seven months. To this number may be added one occurring in private practice, in consultation with my friend Dr. McCreery, making a total of nine. When it is also stated that in these herniotomy was successfully performed, we can scarcely go farther in estimating the results of a desirable experience. It has occurred to me that, with the risk of not presenting anything strikingly novel to the surgeon, some remarks addressed to the general practitioner, and based upon personal experience in these and other cases, might under present circumstances be acceptable.

A leading physician in a rural district once remarked that it was always interesting to him to learn what was the treatment of the ordinary diseases in the large metropolitan hospitals. Even the details of such practices, commonplace as they might appear to be, were assurances to him that nothing better was known. With a view also of making a contribution from such a standpoint these cases are presented, in the hope that the consideration of some practical points connected with them may elicit discussion. It is not proposed to give more than a brief outline of their histories. In so doing I have availed myself of the notes of Dr. J. H. B. Browning, House-Surgeon to St. Francis' Hospital.

It is presumably unnecessary to say that in all these cases there were well marked symptoms of strangulation, inability to return the gut by judicious taxis, and unmistakable local evidences of firm constriction of the gut itself demonstrated by the operations.

Case I.—Jacob P——, aged forty, was admitted to St. Francis' Hospital, New York, March 4, 1884, the third day after the appearance of symptoms of strangulated hernia. Vomiting was stercoraceous, pulse small, features pinched, surface cool, with other symptoms of general prostration. The hernial tumor in the right groin was not noticed by the patient until immediately after a strain, three days before. The patient was etherized, and judicious taxis having failed, herniotomy was performed without delay. A single knuckle of small intestine was involved. Its surface was of a brownish hue, was mottled with extravasations, but at no point was it gangrenous. After dividing the point of constriction at the neck of the sac, the circulation of the gut was restored under the application of hot moist towels, and the hernia duly returned. The wound healed by first intention, and the patient was discharged well, April 2, 1884, with the advice to maintain inguinal support for a period of several months.

Case II.—Catharine B——, aged sixty-five, was admitted to the same hospital, March 15, 1884, with so-called dyspeptic symptoms, associated with a tumor in the left groin. A careful examination revealed the existence of an irreducible femoral hernia, but the patient could give no intelligible account of symptoms of strangulation. In the course of a few hours persistent vomiting with colicky pains occurred. It was then ascertained that these were the dyspeptic symptoms from which she had suffered for the previous two days, and that up to that time she had been able to "put the bowel back." In short, the case turned out to be one of strangulated femoral hernia, and was operated upon without delay.

The gut was found to be gangrenous at a point where it impinged upon the edge of the unyielding crural opening. The sloughing portion was removed, the edges of the wound in the gut closed, and in turn attached to the margin of the ring. The two or three lower stitches of the wound gave way at the end of the fourth day, and through the opening thus made there was a small discharge of fecal matter. By means of compress dressings the fecal fistula closed after a week or more, the remaining wound healing by granulation. This patient, just as she was ready to leave the hospital at the end of the fifteenth day, was seized with a double pneumonia, from which she died on the third day. This, it is true, was a case of death, but not as the result of a successful operation, as the grim humor of an old saw might have it.

Case III. was that of G. P——, aged seventy-three. He was admitted to St. Francis' Hospital March 27, 1884. Two days before, an old inguinal hernia on the left side had come down after a slight strain, and could not be returned. A physician was sent for who made vigorous efforts at taxis. Vomiting then took place, and continued more or less until he was seen in the ward. The hernial tumor was very tender and turgid. The pulse was very feeble, and the patient was quite exhausted. The stricture, which was at the neck of the sac, was divided, and the mahogany-colored gut was nursed in hot moist cloths for a full half hour before it could be returned. The wound healed by second intention, the granulations and subsequent cicatrization completely plugging up the hernial opening. The case progressed without a bad symptom, notwithstanding the bowels did not move until the fourteenth day after the operation.

Case IV.—John B——, aged forty-one, was admitted to St. Francis' Hospital, April 23, 1884. The day before, while in the act of lifting a heavy box, an old hernia in his left groin was forced down, and became very hard and immovable. Pain and emesis occurred two hours after, and continued at short intervals during the following night. Stercoraceous material was being vomited on admission. The usual signs of strangulation were present. Fortunately, but little taxis had been employed outside the ward. Herniotomy was performed without delay. One large knuckle of gut was found to be firmly constricted, diffusely mottled, and mahogany colored. Wound healed by first intention. Patient discharged, May 25, 1884.

Case V.—James R——, aged sixty-one, began to suffer from strangulation of an old hernia on the morning of May 10, 1884, and was admitted twelve hours after with well-pronounced symptoms, including stercoraceous vomiting. There had been so much taxis employed previous to admission that the parts were much swollen, inflamed, and tender. Portions of gut and omentum were involved in strangulation. The gut, when exposed, was found to be of a dull brownish color, and somewhat œdematous. The fluid in the sac was dark-colored. Omentum was deeply congested. Circulation in gut restored under hot applications. The strangulated omentum, which was of small size, was duly excised. The day after operation the temperature was 101½° F. Subsequently there was nothing worthy of note, save that the stitches gave way in the wound, the latter closing by granulation, and apparently permanently curing the hernia. The bowels moved on the seventh day. Patient was discharged June 9, 1884.

Case VI.—Theodore J——, aged sixty-two, had an old inguinal hernia also, which became strangulated after a violent effort at coughing, on June 10, 1884. He was admitted to the hospital the same day in an extreme state of prostration from a persistent vomiting of several hours. Herniotomy was performed within eighteen hours after the accident. A large knuckle of gut was in a dark-brownish, mottled condition, but its circulation was duly restored under application of towels wrung out of hot water. A portion of omentum, also strangulated, was ligated and removed. The wound healed by granulation. Patient was discharged, apparently radically cured of hernia, August 3, 1884.

Case VII.—F. W——, aged forty years, while lifting forced down an old inguinal hernia, which became strangulated. Within a very little while after the accident he grew faint, was nauseated, and vomited the stomach con-

[1] Read before the Practitioners' Society of New York, November 7, 1884.

tents. In spite of a determination to continue at his work he was forced to go home, when vomiting recurred and continued more or less for two days. When admitted to hospital at the end of that period, August 20, 1884, he was much exhausted. He was unable to retain water in his stomach, and the slightest movement was attended with a retching gulp. Herniotomy was performed as soon as the patient could be anæsthetized, forty-nine hours after strangulation. The gut, which was a single knuckle, was firmly constricted in its whole circumference, but not gangrenous. The wound healed by first intention, and the patient, when discharged, September 15, 1884, gave no evidences of a return of the hernia. The bowels moved naturally on the fifth day.

Case VIII.—A. G——, aged eighteen, while adjusting a portion of the load on his truck felt a giving way in his right groin, and immediately after found a good-sized oblong tumor extending into his scrotum. Feeling very faint, and suffering from considerable pain, he went to his home. There the pain increased and free emesis occurred. A physician was sent for, who, recognizing the condition, attempted to reduce the gut and failed. The patient was allowed to rest until next day, when efforts at taxis were renewed, also without avail. Vomiting by this time had become so violent and persistent that the patient was sent to the hospital, after having suffered from symptoms of strangulation for three days. The diagnosis of congenital strangulated hernia was then made and subsequently confirmed.

On slitting open the sac there was a gush of dark venous blood, which came from the previous rupture of a vein in a large mass of strangulated omentum. Together with this epiplocele there was an œdematous, ashy-colored, mottled knuckle of gut, which at first sight appeared to be hopelessly gangrenous. The omentum, which had forced its way into the sac of the tunica vaginalis, was withdrawn, and found to be so suspiciously mottled and inflamed that its veins were at first carefully ligated separately and then *en masse*, and the whole was cut off. This portion of omentum measured 15¼ inches in one diameter, and 8½ in another. The omental stump was used as a plug for the hernial canal. There were recent adhesions between the strangulated gut, which were carefully severed. It required fully twenty-five minutes of soakage of the gut in hot, moist towels to insure its being in a proper condition for return. The wound, on account of previous inflammation around it, did not close by first intention throughout. It opened at its lower portion, and eventually healed by granulation, leaving the hernia, as I believe, radically cured. The bowels moved on the ninth day.

When Dr. Browning, the House-Surgeon of St. Francis' Hospital, called on me with the foregoing histories, which he had kindly prepared for my perusal, I found that there were but eight cases instead of nine, as I expected. By a curious coincidence my friend and neighbor, Dr. J. A. McCreery, called the same morning (October 13, 1884), asking me to operate on the following case of strangulated femoral hernia in his practice:

Case IX.—Mrs. M——, aged thirty-five years, had suffered from a reducible femoral hernia for years, wearing a truss most of that time. On the evening of the day before she was seized with a severe fit of vomiting, which she thought was due to the gastric disturbances of pregnancy, she being three months advanced in that condition. When she recovered from the attack, she discovered that the hernia was much larger and immovable. After several fruitless attempts to return the gut she summoned Dr. McCreery, who in turn asked me to see her with him. I did so without delay, discovered a strangulated femoral hernia, and performed herniotomy at once, with the result of relieving immediately all the urgent symptoms. The sac contained darkly colored gut and a small nodule of omentum. These were both restored, and returned after the stricture was liberated. The patient has made a perfect recovery.

So much for the synopsis of the cases. It is always worth our while in noting successes to explain, as best we can, the reasons for them. Even if for the most part they be not new, they have at least the merit of being true, thus adding weight to practical experience. Such, at least, is a healthy offset to methods which may be new, and yet not true. But let us remark on the matter, in a general way, that we may take a short cut to conclusions.

My experience with cases of strangulated hernia has taught me that taxis is very much overdone. Hardly a case comes to us which is not the worse for it. The temptation to use more or less force is too great for most men to resist. The late Professor Gilman, in his admirably impressive lectures on obstetrics, would charge his hearers not to grasp the cord in attempting to deliver the placenta. "If you have a temptation to pull it, it is better not to touch it at all." Discreet teachers of surgery tell their students to use only a soft catheter to empty the bladder, and for a like reason. Few beginners understand what is meant by merely guiding a solid instrument through the deep urethra, as there is almost always an irresistible tendency to push it along its course. I would say to the practitioner who is not prepared to operate for strangulated hernia, that a safe rule is not to persist in taxis after the first judiciously gentle efforts at reduction. If he goes beyond this he rarely appreciates how much force he is apt to employ before he is willing to give up the fight to another. The patient generally has the best chance with no taxis at all until he is etherized for a possible herniotomy. No time is thus lost, and the operation can be performed as soon as it is decided that taxis availeth not.

Every one knows the rule to operate at once on an irreducible strangulated hernia. This goes without the saying. I am convinced, however, that there are many who do not appreciate its full force, even when cases are recognized early. There seems to be a temptation to hope against hope that an operation may be avoided. And yet the operation in itself is not dangerous. Even in case of doubt in diagnosis, and there are not a few of such to which this remark will apply, it is safer to herniotomize the patient than to let him alone, trusting to chances. Every practitioner of large experience can call to mind cases mistaken up to the last moment, when hope for saving has virtually passed, and when herniotomy is blamed for throwing the balance on the wrong side.

Even such cases should not, however, be looked upon as absolutely desperate ones. Mr. Birkett refers to a femoral hernia which had been strangulated for fourteen days, and upon which successful herniotomy was finally performed. In view of this fact it is the duty of every surgeon to operate upon cases of long-continued strangulation, unless the patient be actually moribund at the time. In one of the successful cases reported the symptoms had lasted for forty-nine hours.

It is, of course, not always easy to decide whether or no strangulation actually exists. The rule should always be to give the benefit of the doubt to the operation, and act promptly. The main tests for strangulation are pain, tenderness, and continuous vomiting, with a recently irreducible hernial tumor. Men in hospital practice, who see a great deal of hernia, always examine the groin when persistent vomiting exists. The candidate at hospital examination who would neglect to mention vomiting as a symptom of strangulated hernia would get a black mark.

To say that herniotomy is a comparatively easy operation might surprise one who has never tried it, and who has timidly folded his knowledge in the seven anatomical layers. Certain drawbacks are naturally to be expected, and should be overcome on general principles. Living anatomy has a way sometimes of dodging the perceptions of the most expert operator. In herniotomy it is the rule. The layers are always ready to compromise their individuality under a becomingly cautious use of the director. The main thing to be sure of is when

the sac is reached, no matter whether the operator divides six or six times six layers before he gets to it. And sometimes in very old hernias he can take his choice.

The making of clean, free cuts, and always in the same line, invariably gives the best results. As a rule I prefer to open the sac, as I believe it does not add to the gravity of the operation, while it insures safety in other directions. I have not seen a case in which I was willing to do otherwise, and I do not believe I have lost one in consequence.

Too much stress cannot be laid upon the necessity of having the strangulated portion of gut in the best possible condition before returning it into the abdomen. Time is well spent in such endeavors. Nothing will accomplish the end in view more efficiently than the direct application of towels wrung out in a hot antiseptic solution. I have kept a suspicious knuckle of gut covered by turns in this way for nearly an hour, with the result of a perfect restoration of the circulation.

In the treatment of this as well as any other operation wound, the indications for cleanliness, drainage, and rest are carefully followed, nothing more. I have never believed that the antiseptic spray was necessary for a good result in any operation. You gain every bit as much, and with half the trouble, by thoroughly irrigating the wound with an antiseptic solution after the operation is completed. Corrosive sublimate solution (in the proportion of 1–1500) was used in my cases in this way.

I do not think it is a calamity for a herniotomy wound not to heal by first intention, as by granulation and subsequent cicatrization the hernial opening and sac are more likely to become occluded. The aim is, of course, for first intention. While closing the wound, and after inserting a decalcified drainage-tube, it is well to take several deep stitches through the entire substance of the sac at different points, with the chance of exciting adhesive inflammation, and thus obliterating the sac cavity. I succeeded by this method in four cases. After closing the wound, firm pressure is maintained, upon a warm, thick, moistened pad of sublimated gauze, by means of an ordinary spica bandage. The dressings are not disturbed as long as the temperature is normal, or until the wound is healed.

Partly as a precautionary measure against traumatic peritonitis, but principally for purpose of absolute rest, my patients are kept under the influence of morphine during the first four or five days after the operation. The bowels generally take care of themselves, and require no help unless evidences of intestinal irritation manifest themselves. One of the cases did not obtain an evacuation until the end of the fourteenth day, and made no complaint because he thought it was natural under the circumstances.

247 Lexington Avenue.

The Antidote Bag.—Mr. Martindale, of London, who was the first to adopt a suggestion to produce a bag fitted with every remedy and appliance likely to be needed in the treatment of a case of poisoning, has now further improved upon it by omitting some articles, as the stomach-pump, enema, catheter, etc., which are always at hand, and has thus not only rendered the bag more portable, but has been enabled to supply it at a greatly reduced cost. This smaller bag contains the following antidotes, which are labeled with directions for their use, viz.: dialysed iron, syrup of chloral, chloroform, aromatic spirit of ammonia, spirit of chloroform, oil of turpentine, acetic acid, tincture of digitalis, nitrite of amyl capsules, sulphate of zinc, ipecacuanha, bromide of potassium, calcined magnesia, tannin, and a hypodermic case with syringe and solutions of acetate of morphia, apomorphia, nitrate of philocarpine, sulphate of atropia, and nitrate of strychnine.—*London Lancet*, September 27, 1884.

SOME NEW FACTS AND CONSIDERATIONS IN THE DIAGNOSIS OF CANCER OF THE STOMACH AND CANCER OF THE PANCREAS.

By MIDDLETON GOLDSMITH, M.D.,

RUTLAND, VT.,

BREVET LIEUTENANT-COLONEL AND SURGEON, FORMERLY PROFESSOR OF SURGERY IN CASTLETON MEDICAL COLLEGE, AND HONORARY MEMBER OF THE NEW YORK PATHOLOGICAL SOCIETY, ETC., ETC.

It is pretty generally and well agreed that the diagnosis of primary cancer of the pancreas is always uncertain, if indeed it is ever possible; or, in other words, there are no agreed-upon signs surely diagnosing primary cancer of the pancreas. About the sum and substance of what our best diagnosticians lay down is to the effect that a painful tumor in the epigastrium, unattended by gastric derangement, such as anorexia, vomiting of coffee-ground like ejecta, or even bloodless vomiting, pain after eating, etc., may be set down as cancer of the pancreas.

When it is remembered that there are many cases of cancer that present during life no symptoms of gastric disturbance and no signs of epigastric tumor, it is apparent that the foregoing is not very reliable; and still further, when it is remembered that a cancer of the pancreas may exist and have the exact symptoms of simple stomach cancer minus only the hemorrhage, the physician attempting to determine as between cancer of the pancreas and cancer of the pylorus is adrift without a star or compass to guide him.

Now, it so happens that within the last two years I have met with three cases, one of cancer of the stomach, which had but one certain symptom and that one not laid down in the books; and also two cases of primary cancer of the pancreas, both of which had a symptom by which they could be diagnosed.

A Mr. B——, a butcher by occupation, aged between fifty and sixty years, for more than a year had been ailing. About two months before his death he consulted me on several occasions. His appetite was pretty uniformly good; his digestion was good to all appearance; he had no pain in his epigastrium; he had no coffee-ground vomiting, and indeed had vomited but once in six months. There was no tumor in the epigastrium. The abdomen was flat, collapsed like one suffering from chronic diarrhœa, and flexible all over save that at the epigastrium, and for a hand's breadth below the ensiform cartilage, the abdominal wall, from costal margin to costal margin, felt like a concave bridge of sole leather and unyielding to moderate pressure. Percussion was not dull enough, I thought at the time, for an hypertrophied left lobe of the liver. The patient's face had the look of a marked cancerous cachexia. *He had a peculiar fetor to his eructations.* It was not the rotten-egg odor—nor the odor of any of the ordinary fermentations of food, but the odor was that of the most odorous uterine cancer—once smelled, not easily forgotten. I have never seen this symptom mentioned. It is not a symptom laid down in the books. *Fetor of the breath* is often mentioned, but, as far as my observation has gone, it is not to be relied upon. A bad breath is so common in so many conditions; it comes of so many causes; it is so inconstant to cancer, apart from the indigestion it implies, but not always present in that disease, that it cannot be justly called pathognomonic. The fetid matters in the breath come from the lungs, bronchi, pharynx, mouth, or teeth. The fetor of eructations is from the contents of the stomach. A stomach whose contents would stink when opened after death, barring post-mortem putrefaction, is one from which the eructations might be supposed to give off in life the odors of the stomach opened after death, and before cadaveric putrefaction. Besides, the kind of odor is cancerous in these cases, not putrefactive. The two odors are different and distinguishable. To smell a cancerous womb and then a putrefying cadaver is to learn the distinction.

Inasmuch as many cancerous stomachs opened after

death have no cancerous odor, so many and a large majority of those having cancer during life have not fetid eructations. Yet when the eructations have that canonical fetor, that fetor is pathognomonic. From these considerations, cancer of the stomach was the best guess I could make. It proved to be correct on post-mortem. The left lobe of the liver had become adherent at some time to the stomach, and had been drawn, stretched out and thinned by the stretching, so as to cover the whole space mentioned above as being resistant to pressure. On lifting up the liver, to get at the stomach below, I tore the softened stomach open and there came a whiff of the odor of his eructations, an odor so pungent as to make it necessary for some of us to change our clothes before we could go home to dinner. It was a simple case of soft cancer involving the greater part of the stomach, as well as I could judge from a very brief examination before the autopsy was surrendered to the younger folks then and there present. The microscope proved it to be encephaloid. Now, here was a case of outrageous gastric cancer with not a single symptom peculiar to it save one, which attaches not so much to the organ diseased as the putrefaction of the matters contained in it, and that not one of the symptoms laid down by authors. Nor does this case stand alone. I remember seeing a cadaver placed on table for examination in Louisville, a good many years ago, in which the diagnosis had been pernicious anæmia, the case having not shown a single symptom belonging to cancer of the stomach. I remember the surprise with which the cancer of the stomach was greeted. There are on record a good many cases of this kind besides Abercrombie's celebrated one. So that it may be said there are in some cases of cancer of the stomach no stomach symptoms to exclude.

Of the two cases of pancreatic cancer, the first was that of a healthy-looking, spare little woman who came to me from Indiana for the treatment of what proved to be gall-stones. She had the usual symptoms which attend upon the passage of gall-stones from the gall-bladder, as well as the dark urine or the icterus which follow it. She was one of the few persons whom I have met in whom the projecting gall-bladder felt like a bag of beans. She passed large numbers of faceted calculi as well as some crystallizing and jagged specimens, which had not been long residents of the gall-bladder.

Along toward what seemed to be the approach to convalesence from the gall-stones, the appetite, which heretofore had been good, began to fail. Her pains, which had heretofore been at intervals (marking the passage of gall-stones), came to be continuous and gradually grew to be more and more intolerable. She had vomiting, but there was no blood in the vomit, she had an intensely sour stomach, gastric catarrh, and constipation. There was no increase of the stomach pain after eating.

Meanwhile her face began to show a cachectic look. About this time I thought I could perceive a very small hard lump a little below the pylorus when the stomach was not full of food. The tumor would always disappear after eating a full meal. This little tumor was hard, and somewhat painful to the touch. It was fixed. It did not ascend or descend, or otherwise alter its position as tumors of the pylorus do sometimes. All the while the patient kept taking opium to keep the pain subdued. But for all that the face, besides its cancerous suggestion, showed that cast of expression whose only name is the cachexia of pain. Then came a curious semi-delirium, with a far-off look which I have seen but twice. The most careful inquiry elicited no signs of fatty stools. There could be found no tumor of the liver, no disease of any other portion of the body; there were no glandular enlargements. So that I was compelled to the diagnosis of primary cancer of the spleen in addition to gall-stones.

After death, which occurred some six months subsequent to the discovery of the little neoplasm, below the pylorus, we found the liver (save a number of gall-stones in it) and the abdominal viscera healthy. There was no disease of the stomach save extreme atrophy, and the little tumor of the pancreas proved, under the microscope, to be a spindle-celled carcinoma. . . .

The third case was that of a Mrs. H——, living at that time at Factory Point, some thirty miles from Rutland. I saw her twice. I found her greatly emaciated and quite feeble. She had anorexia, occasional vomiting, and pain about the pylorus after eating. She stated that her pains were not *all* related to the times of eating, but she had other and greater pains during the night, which were sometimes relieved by changes of position, but would often endure all night.

When I first felt the epigastrium, she being recumbent, and the stomach empty, I found a tumor apparently about as big as a pullet's egg. The lump was round, hard, and to the touch nodular. It was painful to the touch, and seemingly could not be moved. Of that, however, I was not so sure, because manipulation hurt her so much I did not push this branch of the inquiry. I did not see the matters vomited, or notice the drooling her doctor afterward told me about. Her attendant had noticed nothing unusual in her stools or vomit.

At my next visit the symptoms were unchanged, except her body was failing and *no tumor could be felt in the epigastrium.* I found out after her death that on the morning when I first saw her she had eaten nothing, and that at my last visit she had just taken her usual meal. The trains would arrive at Rutland a little after 11 A.M., and arrive at Factory Point a little after 12 M., so that my arrival at the house—about a mile from the railroad station—would occur commonly about a quarter past twelve and half-past twelve—and half-past twelve is the canonical dinner hour for all Vermont.

The following is a history of the case from Dr. Wyman, of Factory Point, who, though not at the time in attendance, had seen of her more than her later physician:

"Last April she first consulted me in regard to her not being well. She complained of a neuralgic or rheumatic pain in the left side under the short ribs, and in the pit of the stomach. She had no appetite—guessed she was 'lazy,' as she was weak and tired. I prescribed for her two or three times during the month.

"In May she appeared about the same, only the pain in the side was at times worse. She had spells of it about 10 o'clock A.M., and I learned her nights were sleepless, and often she could not lie down on account of the pain. It was worse three or four hours after eating. She looked sallow and tired. The pain was dull and constant, at times more severe. It would start in the left hypochondrium, or a little above, and extend to just below the ensiform cartilage, and the space there was tender to pressure. She complained also of pain under the right shoulder-blade. Her bowels were regular, urine normal, tongue not coated, but color a little too dark, but not purplish. She seemed almost like one who some time had had malaria (she lived for two or three years, a few years ago, in Central New York), and I thought, perhaps, there was some remnant of that lurking in her system. So she continued, not very sick, but ailing, growing weaker and thinner; appetite fickle, often a perfect loathing of food; no thirst, and pains about the same until the middle of June, when she was taken worse; pain intense, but more in dorsal region, but alternating between that and side and stomach; quite a relax of the bowels, constant nausea, and once or twice she vomited. The ejecta was simply a watery fluid, slightly tinged yellow. On account of the pain in the back I examined the urine, but as its appearance was so natural I only tested it for sugar and albumen, and found none. The stools she described as being like those which occur in simple diarrhœa, and I did not examine them, as I could not ascertain that there was anything strange about them. I regret now that I did not see them.

"About this time I went West, leaving the case. She

had grown much more comfortable, although she failed very perceptibly during this acute attack. The remedies which I left for her will give you a key to my diagnosis, viz.: Creasote in one-tenth drop doses and arsenicum alb., although a careful examination of the abdominal viscera failed to find any tumor or swelling of any kind, neither any tenderness to pressure in any place except over the cœliac axis or plexus. She urged me while pressing over the stomach and bowels not to be afraid to use as much force as I wanted, as there was no pain resulting. The diarrhœa lasted but a day or two, and then the bowels moved naturally every, or every other day. About ten days after I left her to go away she became fearfully constipated. Dr. Trull was called, and as he attended the case thereafter until death terminated the suffering, he will give you the further report.

"One thing I often noticed. Beside her bed she had lying upon the floor a piece of paper, say ten or twelve inches square, and this would be covered with a thick, viscid, and sometimes frothy sputum. She did not *cough* it, for she had no cough; she did not *vomit* it, for, while under my care, she only vomited at the time mentioned above. She just seemed to 'spit' it as it came into her mouth. And for some reason she seemed remarkably shy in speaking about it. Taking your tabulated symptoms of diagnostic points, I will indicate what symptoms she had while I saw her professionally: Emaciation rather rapid, but not extreme; no tumor in epigastrium; severe pain in epigastrium, side, and back; stools described as natural; no sugar in urine (I mentioned that I tested for albumen, but found none); impaired appetite, disordered digestion; loathing of food; pain worse three or four hours after eating (marked); vomiting but the time mentioned. She had then anorexia, debility, emaciation, a flow of saliva-like fluid from the mouth, cœliac neuralgia; dull, heavy, aching pain deep down in the epigastric region, radiating or extending to the back and lumbar region, *relieved* by *rubbing* and assuming erect position or sitting up in bed; worse by paroxysms and at night; no jaundice, no thirst, no increase in temperature, a slightly increased pulse, a sallow, but not greenish-yellow complexion; urine and stools natural, so far as observed. These constitute the array of symptoms as far as I observed them. Their change Dr. Trull will notice. The family history revealed a cancerous diathesis. Some fourteen years ago she went to you in Rutland, and you removed a tumor from the back of her hand. Have you any recollection or record of its character? The large gall-stone which was found in the gall-bladder I send you by mail with this. Its weight was 3 iss. If you have no further use for it after examining and keeping it as long as you desire, will you kindly return it to me?

"I have thus hurriedly tried to give you the salient points in the case. If I have failed in any of them please interrogate me further. Hoping it will be satisfactory, however, I am, sincerely yours, E. L. Wyman."

Now, here was a woman, about sixty years of age to appearance, with a family history of cancer, with a cachectic look, pale, and rapidly emaciating, with more or less constant pain radiating from the epigastrium, having occasional vomiting and anorexia, and an increase of pain a few hours after eating, and a tumor at the epigastrium. Could there be a plainer case of cancer of the pylorus?

Yet the post-mortem examination showed it to be a case of primary cancer of the pancreas, with *dilatation of the stomach*, and one big non-faceted gall-stone in the gall-bladder.

These two cases are worthy of comment, for in the study of them I think we may find something to make the diagnosis of this confessedly undiagnosable disease possibly diagnosable.

Dr. Jenner says, in effect, no symptoms are pathognomonic of pancreatic disease. Dr. Wardell, in "Reynolds' System of Medicine," vol. iii., p. 428: "Da Costa has professed to diagnose cancer of the pancreas from its other maladies, but the truth is we have no just rules of observance to point out any real distinctions." Da Costa, in his "Medical Diagnosis," p. 605, says: "As regards cancer (of the pancreas) the most trustworthy symptoms are a tumor in the epigastric region, pain in the back, not increased by the taking of food, but usually augmented by the erect posture; progressive emaciation and debility; an appetite capricious rather than diminished, and, in some instances, indeed a ravenous desire for food; constipation at times, but far from invariably." It seems to me that the two cases of primary cancer of the pancreas above related point to a diagnostic rule of great value, so far as two cases can go toward making a rule. In the first case it is to be noticed that the little tumor could be felt almost all the while, and that at the times at which it could not be felt the stomach was distended by recently eaten food. What probably made it possible to feel the tumor at almost any time or any posture was her emaciation, and the small quantity of food in her stomach. The post-mortem examination, in disclosing the atrophy of her stomach, accounts for the fact that her cancer of the pancreas was so seldom overlaid by that viscus distended. In the second case the tumor was seldom felt during life. Indeed I don't think it was felt more than once. When it was felt she was *recumbent*, and had not been eating. The post-mortem in revealing a very considerable distention of the stomach, revealed the reason why, and how the cancer of the pancreas was aproned over most times during life.

Cancer of the pylorus sometimes appears and disappears; I saw one such a case a few years ago. A man, from Salem, N. Y., came to see me on account of a stomach trouble which had been pronounced cancer. On examination of him, as he lay on my operating-table, I could feel no tumor at the epigastrium, and I was inclined to doubt the diagnosis of his former attendant, whom I knew very well, and knew to be a practitioner of considerable ability. I bethought me to make the patient stand up. In an instant the pyloric tumor was there as plain as a pike-staff. I wrote to his attending physician and asked him to follow the case and get a post-mortem if he could. He did, and answered that the case was one of *cancer of the pylorus*, not of the pancreas. But it appears that the *erect* posture brought the pyloric tumor within the region of touch, and in doing so would not have uncovered, but rather hidden a pancreatic cancer.

Hence, in examining a suspected pyloric tumor, the fact that it cannot be felt in conditions which allow the stomach to get over it, and can be felt only when the stomach cannot get in front of it so as to apron it: or, in other words, if the suspected tumor can always be felt when the stomach is empty, but disappears whenever the stomach is distended, and if the tumor commonly is more obvious in the recumbent than in the erect posture, I feel quite confident we should be justified in making the diagnosis of pancreatic tumor even in the presence of some of the symptoms of stomach cancer, such as anorexia, pain after eating, or occasional bloodless vomits. Another diagnostic point which seems to me as of considerable value is the character of the pain as well as its persistence. In the first place, the pain is more continuous than in cancer of the pylorus. In the second place, the pain radiates in more directions than in cancer of the pylorus. In the third place, the pain is more dismal, more dolorous. It is a pain that seemingly has no ending. It is a disheartening pain. It does not become more endurable by having been endured. It is a pain which has no leaven of hope in it. It will be noticed in Mrs. H——'s case that there was pretty constant (for a time) spitting of a saliva-like fluid from the mouth. Frerichs attributes to this symptom considerable importance, but says, "We must be careful in considering such an increased salivary secretion as due to disease of the pancreas, for as yet there are no recorded cases of primary uncomplicated pancreas disease in which this symptom was definitely present" (Fried-

reich, in "Ziemssen's Cyclopædia," vol. viii., p. 567, to whom I must refer the reader for further consideration of the value of this symptom).

P.S.—The writer is not unaware of the extreme rarity of primary cancer of the pancreas. Dr. Putnam, of this place, saw the first case with me, and attended the post-mortem. The other case was witnessed by Drs. Trull, Wyman, and others, I think, at Factory Point, Vt.

JEQUIRITY OPHTHALMIA.[1]

By JOSEPH A. ANDREWS, M.D.,

OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK.

HAVING quite recently[2] considered, at some length, the subject of jequirity ophthalmia, I desire here to limit my remarks to a brief review of certain papers that have appeared on the subject in question since my own communication alluded to above was published.

First, is jequirity directly responsible for the disastrous results which have been placed on record as having followed its use?

Has it a constant and regular action, and are there any dangers to be apprehended from its employment, even according to the directions which I have indicated in my paper (loc. cit., p. 251)?

In order to answer the first question, it will be necessary to examine the evidence which has been adduced to show that jequirity is to blame for the mischief to the eye which has resulted during its use.

Jacobson[3] records a case in which jequirity produced purulent infiltration of the cornea, perforation of the latter, and exposure of the entire iris. This would certainly seem to be a grave reproach to the use of the remedy in question. In this particular case, the ophthalmia produced was certainly not true jequirity ophthalmia, and yet this circumstance would not be a sufficient defence of the remedy; but I am convinced that the real source of mischief is to be sought in the strength of the infusion and the manner in which it was employed, Jacobson having, namely, *instilled* the infusion (five per cent.) into the conjunctival sac, and kept up the action of the drug with compresses wet with the infusion. This was following Dr. de Wecker's first instructions regarding the use of jequirity to the letter; and that Dr. de Wecker obtained uniformly favorable results before he had modified his manner of applying the drug, is certainly very remarkable and providential. But in Dr. Knapp's two cases,[4] although true jequirity ophthalmia was not produced, a violent pyorrhœa having followed the use of the infusion, and affected the other not inoculated eye, nevertheless this case is a most instructive one. Dr. Knapp treated the two cases in question according to Dr. de Wecker's last directions, making a single brushing of a fresh three per cent. solution, macerated for three hours, over the entire upper lid; and yet this single application was followed by violent reaction and perforation of the cornea. If it be possible with jequirity to produce a purulent ophthalmia, then we cannot defend the remedy in a given case in which it has produced mischief by the substitution of a purulent for a genuine jequirity ophthalmia. Nevertheless, I confidently believe that the dangers to be apprehended from the drug may, in a very marked degree, be avoided by observing the strictest caution in its use. The facts which should be seriously borne in mind are, that all eyes are not affected in the same degree by the remedy, a three per cent. infusion in one instance being followed by violent reaction, while in others a stronger infusion may give rise only to slight reaction. Therefore I believe that the safest plan to observe is to begin with a weak solution, say two per cent., even where there is pannus, and one per cent. when the cornea is not involved, and keep in mind the fact that there is a period of incubation which may exceed twenty-four hours. *The berries should be husked, crushed, and macerated for about six hours in cold distilled water, then filtered;* and after a single thorough brushing of the palpebral conjunctiva with cotton wrapped about the end of a match. *Thirty hours are allowed to elapse before* renewing the brushing; then, according to the susceptibility of the patient to the action of the remedy, we may repeat one, two, or three times daily, always proceeding with caution, and *never keep up the action of the drug with compresses wet in the infusion.* By following these directions I have never yet seen an untoward result, and I have used the remedy in one hundred and forty cases of diseases of the cornea and conjunctiva.

Pre-existing purulence is a positive contra-indication to the use of jequirity. Papillary hypertrophy of the conjunctiva is not favorably influenced by the remedy. Hippel says, the more hyperæmic the conjunctiva is, the more intense will be the reaction. De Wecker says this is an error; but from my own observations I feel disposed to believe that Hippel's statement is, in a measure, correct. However, this much is true; the nearer the conjunctiva approaches a normal physiological condition, the more certain and intense will be the impression produced by the infusion. The most violent reaction I have seen follow the use of an infusion of jequirity occurred in a case of sclerosis of the cornea, in which the conjunctiva, for all practical purposes, was normal. But the patient in this instance took upon herself the responsibility of departing from my instructions, and instead of a single application, and awaiting the lapse of the number of hours indicated, she *poured* the infusion (three per cent., cold, macerated for six hours) into the eye four times during the day. The result was a most intense chemosis and swelling of the lids and corresponding side of the face, and nasal mucous membrane; and in the region of the frontal sinus the pain was so violent that the patient declared that she did not sleep for three nights; and I am convinced that her suffering must have been very acute.

With violent inflammatory reaction there was extensive formation of a croupo-diphtheroid membrane, and a resulting symblepharon, and what is most instructive for us to remember is the circumstance that it was a case of genuine jequirity ophthalmia, no purulence having occurred at any time in the course of the inflammation. And yet the vision was improved from an ability to perceive light, to counting fingers at fifteen feet.

Dr. de Wecker says,[5] "without any doubt, the cornea is not exposed to any danger" in jequirity ophthalmia. But the first case in which I employed the remedy taught me that this was a most pernicious error, and that the cornea is endangered. However, if we compare the number of authors who have declared themselves for and against the jequirity treatment, we find that the former are conspicuously predominant, and it would seem that those authors who do not favor the remedy, such as Vossius, Galezowski, and Nicolini, might change their views if their experience were extended to a larger number of selected cases.

Scrofulous pannus and sclerosis of the cornea are favorably influenced by jequirity, and I have had very gratifying results in this class of cases in improving the vision; but I have never used the remedy, as Dr. Wecker has, in torpid ulcers of the cornea, firstly, because I could not satisfy myself that the cornea was not placed in still greater danger by its use; and secondly, I felt that I could rely on safer and really more satisfactory means. However, of course, mere conjecture should not be permitted to weigh against the results of experience, and Dr. de Wecker's experience seems to speak in favor of the remedy in this class of cases.

40 WEST TWENTY-FOURTH STREET.

Progress of Medical Science.

New Treatment of Strangulated Hæmorrhoids.—Dr. Monod advises a new treatment for strangulated hæmorrhoids, which he has practised with great success. It consists in forcibly dilating the anus, as in case of fissure. Verneuil had already recommended this method for the cure of simple piles, and has been followed by most of the young surgeons, who have entirely abandoned every other treatment. To effect the dilatation Verneuil employed specula of different dimensions, and only in the case, as has been just stated, of the ordinary condition of hæmorrhoids. On the contrary, he says that "when the piles are the seat of sphacelus he always waited until the complication disappeared." Monod, who has imitated Verneuil with the best results in those simple cases, goes still farther, and instead of regarding strangulation as a counter-indication to the operation, considers that his fact renders it the more necessary. He cites a case n point. He was called by one of his *confrères* to see a gentleman who had been suffering excruciating agony for two days from strangulated piles, and on whom ice fomentations, narcotics *intus* and *extra* were tried without effect. Local examination showed no more than is ordinary in such cases—a ring of tumefied external hæmorrhoids surrounding a packet of internal turgescent hæmorrhoids, with a dark spot in the centre, announcing the commencement of sphacelus. The least touch was painful, and the patient demanded relief at any price. Partisan of the treatment of hæmorrhoids in general by dilatation, he thought that he would be doing right in employing it in the present case, knowing that by suppressing the action of the sphincter the pain would cease. Accordingly, the patient was put under the influence of chloroform, and the hemorrhoidal tumors reduced, and then Monod largely dilated the anus with his fingers. A few minutes afterward the patient awoke free from all pain, and in a few days he had the satisfaction of not only feeling that the strangulation had entirely disappeared, but that he was for ever quit of his piles. This case of Monod's proves that the hand dilates just as well as the speculum, and consequently the operation is reduced to its simplest expression.—*Medical Press*, September 24, 1884.

Naphthaline in Diarrhœa and Cystitis.—For the last three years Professor Rossbach, of Jena, has employed naphthaline in all the cases of diarrhœa that have come under his care. He concludes that it is of great service in all cases of chronic intestinal catarrh, with or without ulceration, attended by chronic diarrhœa, and in all cases the stools in the course of from five to fifteen days become of normal frequency and consistence. Some of the naphthaline given passes over into the urine, and the effect in the case of urinary troubles was noted to be exceedingly favorable. Pus, blood, and vibriones quickly disappeared from the urine after its administration. It was given in doses of thirty to forty-five grains per day. After half a grain daily the appetite was often improved. —*The Medical Press*, October 15, 1884.

Migraine and Tabes.—Among the various prodromal symptoms of tabes dorsalis, attention was drawn by Duchenne, and later by Pierret, to the occurrence of neuralgic seizures closely simulating hemicrania. The recent brochure of Berger mentioned this fact as a novel observation. Dr. H. Oppenheim, of the Berlin Charité, points out (*Berl. Klin. Wochenschr.*, No. 38, 1884) the priority of the French authors, and supplies some interesting details of twelve cases, from a total of eighty-five tabetics, who either were at the time of observation or had previously been subject to migraine, ten of the patients being females. The study of these cases leads him to conclude that hemicrania is far too frequent a feature in the history of tabes dorsalis to be considered an accidental event, and that it is far more common among tabetic women—*e.g.*, ten times in thirty-two cases—than among men. The relations which the hemicrania bears to tabes are various. Generally it has been present many years before the initial symptoms of tabes, and the hemicranial attacks increase in frequency, intensity, and duration as the disease advances. Or the migraine may coincide with the onset of declared tabetic symptoms, or be associated with vomiting and gastric crises. In rare cases the hemicrania does not appear until tabes is developed. On these grounds, Oppenheim thinks it the duty of the physician, especially in migraine of increasing severity, to be on the alert for the recognized early symptoms of tabes—especially the absence of knee-jerk.

Tonsillotomy.—Dr. de Saint-Germain, believes that the tonsillitome of Velpeau, also of Luer, are very unsatisfactory instruments, and better not used. The operation is frequently incomplete, and the tonsils are often left untouched. The best method is removal by means of a straight bistoury. The tonsils should be held firm in a pair of forceps. An incision made close to the edges of the instrument by means of a bistoury removes the entire tonsil without any danger of injuring either the palate or the pillars. When the right tonsil is removed, the left hand must perform the operation, which is decidedly inconvenient. Amygdalotomy thus performed on children is never followed by accidents, nor by hemorrhage of an alarming nature. The author mentions instances where excision of the tonsils among adults provoked hemorrhage, which resulted in the death of the patient. In young girls, fourteen or fifteen years of age, who have not menstruated, the tonsils ought not to be removed; the hypertrophy frequently disappears after the menses appear. Dr. de Saint-Germain affirms that the tonsils ought not to be removed, unless by their size they impede free breathing.

The Symptomatic Treatment of Typhoid Fever. —Professor Ebstein read a paper on "The Treatment of Typhoid Fever," at the recent meeting of the German Scientific Association, at Magdeburg. He gave his experience for the past seven and a half years, at the Clinic, in Holstein. The number of cases treated was 235. The mortality was only 5.5 per cent., reduced to 2.5 per cent. by the exclusion of inevitably fatal cases. The author concludes that the so-called "abortive treatment" with calomel is useful and to be recommended. In the absence of any causal treatment, this can only be symptomatic, *i.e.*, measures based on a consideration of the morbid phenomena and individual conditions. Above all, attention must be paid to judicious dietetic treatment and the maintenance of the nutrition of the patient. The control of high temperatures, even if of long duration, is only called for when they are associated with severe cardiac or nerve symptoms, or when the temperature attains such a height as to threaten life. The principles of treatment enunciated are, says Ebstein, far more satisfactory in practice and in their results than an exclusive adoption of "bath treatment," or other methods of strict antipyresis. Baths he regards as of value for their powerful stimulant action, and he would employ them where other methods seem to be insufficient.—*London Lancet*, October 18, 1884.

The Germ-Theory of Malaria.—In a paper read by Dr. Hart, of Arkansas, before the Medical Society of his State (*Gaillard's Medical Journal*, September, 1884), he asks some rather pertinent questions of the believers in the bacillus malariæ. He wishes to be enlightened on the following points: 1. How does the bacillus malariæ generate, thrive, and prosper under such diverse circumstances and surroundings? 2. How can it manifest itself in such diversified effects, and produce so many different diseases? 3. Will not the same pathogenetic cause always produce the same disease as its effect? 4. Will different bacilli produce the same diseases? 5. It will not do to invoke the aid of any other bacillus to do the work of the malarial bacillus, though the existence of

fifty or a thousand others be proven. 6. If there be a bacillus malariæ, and quinine be its destroyer or germicide, why is it not equally effective and potent in all diseases produced by it? 7. To determine the existence of a malarial bacillus three propositions must be proven and established: First, it must be discovered; second, it must be cultivated; third, it must be capable of being reproduced. 8. The existence of a germ determined and established as above, three propositions must be proven to establish its causative relation to malarial disease: First, that it will always produce the same disease and nothing besides; second, that nothing else will produce it; third, that malarial disease will always be produced by it and nothing else. The above propositions, he concludes, must be proven to a demonstration to establish the existence and causative relation of germs to malarial disease, and without this proof palmella spores and algæ, and pyrogen and pigmentary elements, and all the bacillus twaddle of germ theorists, amounts to nought, and is but fit rubbish for the waste-basket.

The Removal of Tattoo Marks.—India-ink markings in the skin are often the source of much annoyance in after life to those who have been tattooed in youth. The editor of the *Medical Press* states that nothing but the knife or an active escharotic will produce a satisfactory result. He holds that the cutis must be destroyed. Dr. Neale, of London, however, claims that he has secured good results with sodii ethylas, first suggested by Dr. B. W. Richardson. He cites the case of a gentleman who, in his younger days, had a palm tree tattooed on his arm and an elaborate bracelet on his wrist, who has quite lost all the dark matter, etc., the skin being left in many places quite natural, although, of course, there is still more or less of a scar, but this diminishes month by month.

Resorption of a Pleuritic Effusion following Erysipelas of the Chest.—Dr. M. Schmidt relates the case of a strong man, fifty-five years of age, who was admitted to hospital suffering from pleurisy with effusion. He was treated by poultices to the chest and opium internally, and subsequently by the application of a large blister. No improvement followed, but about a week later the temperature suddenly ran up and an erysipelas began, starting from the wound of the blister, and soon spreading to the entire surface of the chest both front and back. Four days subsequently it was found that the effusion had almost entirely disappeared. The erysipelas attacked the head but finally yielded and the patient made a good recovery. The author does not advocate Fehleysen's practice of inoculating the patient with erysipelas in order to promote absorption of the fluid, as one death has been thus caused. But he thinks that by means of Pasteur's method of culture and attenuation it might be possible to obtain a modified virus which could be inoculated with entire safety.—*L'Union Médicale*, September 25, 1884.

Ephemeral Rheumatismal Periostitis.—At the recent meeting of the French Association for the Advancement of Science at Blois (*L'Union Médicale*, No. 133, 1884), Professor Verneuil read a paper on an affection not hitherto described in the text-books, but of which he had observed two examples. The disease presents under the form of a tumefaction, hard at first, but becoming elastic and soft after a certain time. At one period the sense of fluctuation was so marked that it was thought that pus was present, but the fluctuation disappeared and the swelling gradually subsided. There was no hyperplasia as in ordinary surgical periostitis, no fever, and no discoloration of the skin. At certain points the swelling disappeared spontaneously, at others it at first diminished and then increased again in size. There was in the latter case a very appreciable congestive element, for one of the patients having taken cold, a tumor situated on his face increased suddenly to twice its former volume. There was no previous history of syphilis, but the patients had repeatedly had rheumatism. As usually happens when cases are related of previously undescribed conditions, many of the members present had seen similar cases, and they related the histories of their several patients, which agreed in general with those described by the author of the paper. Professor Verneuil proposed to call the affection ephemeral rheumatismal periostitis.

Palliation of Epilepsy by Apomorphia.—It is stated in the *Revue Médicale* of September 20, 1884, that a German physician has succeeded in cutting short epileptic attacks by subcutaneous injections of muriate of apomorphia. He injected three or four drops of a one per cent. solution. The patients experienced some nausea but there was no vomiting. Whenever the injection was made during the aura the impending convulsion was nearly or entirely averted, and the more prolonged the aura usually was, the more pronounced was the success of the injections.

Decoction of Valerian in the Treatment of Contusions.—Upon the suggestion of Dr. Grehant, Dr. Aragon has made a number of trials to determine the value of a decoction of valerian root as a dressing for wounds, and especially for contused wounds. The decoction used was of the strength of thirty grammes of valerian root to one litre of water. The cure was no more rapid than that which obtains with other dressings, but from the first application the pain was completely abolished. This is a point of considerable importance if it should prove to be sustained in further trials.—*Lyon Médical*, September 21, 1884.

Treatment of Elephantiasis by Electricity.—Dr. Vicira de Mello has recently published a monograph on this affection, based upon the study of upward of one hundred and fifty cases. He shows that the causes capable of producing lymphangitis are also the causes of elephantiasis, since the latter is developed in consequence of successive attacks of lymphangitis. This accounts also for the comparative frequency of the affection in warm countries where the causes of external irritation are so numerous. During the attacks of lymphangitis the lymph transudes into the subcutaneous tissues, and is not there absorbed. The surrounding parts are chronically inflamed, proliferation takes place, and after several successive attacks of this nature the elephantiasis becomes established. Death from elephantiasis is of very exceptional occurrence, due to abscess or some other complication. The author has never observed the termination by gangrene, as is mentioned by some pathologists. The attacks of lymphangitis are usually treated by the administration of quinine in large doses, purgatives, and locally by antiseptic applications. But Dr. de Mello asserts that the only method of treatment which has given any satisfaction in elephantiasis is that by electricity. He has employed both galvanic and faradic electricity with excellent results, and in this his experience is in accord with that of Drs. Silva Aranjo and Moncorve.—*Journal de Médicine de Paris*, October 4, 1884.

How to Shrink Hypertrophied Tonsils by Caustic Applications.—Among the various caustics for local use in causing shrinkage of tonsillar hypertrophies, Dr. Chisholm (*Virginia Medical Monthly*) has found the chloride of zinc the most available and the least annoying to the patient. He employs it in the following manner: A wire, the size of a fine knitting-needle, is roughened for a half inch from one end, so that it may hold a fibre of absorbent cotton twisted upon it. Dip this into a saturated solution of chloride of zinc, and thrust it to the very bottom of the crypt, and keep it there several seconds. When withdrawn the whitened orifice marks the cauterization. By renewing the cotton for each follicle, several may be thoroughly cauterized at the same sitting, without causing any annoying irritation to the throat. A very few applications will cause the gland to shrink, as will be seen one week after the destructive cauterization has been made to the interior of the follicles.

Explosive Drugs.—Several instances are related in the *Deutsche Medicinal-Zeitung* of September 29, 1884, of injuries resulting from the explosion of compounds ordered in physicians' prescriptions. A gargle was ordered of chlorate of potassium, chloride of iron, and glycerine. It was prepared, and five minutes later the bottle exploded in the purchaser's pocket, wounding him quite severely with the fragments of glass. A mixture of hypophosphite of lime, chlorate of potassium, and lactate of iron exploded and nearly killed the prescription clerk who was componnding it. Even the simple trituration of calcium hypophosphite is dangerous; a young pharmaceutist was killed by an explosion which was caused by the shaking of a solution of this substance. Physicians not infrequently order a solution of chromic acid in glycerine. But when the acid is added quickly and all at once to the glycerine a readily explosive substance like nitro-glycerine is formed. Chlorate of potassium when mixed with tannin or muriate of morphia often explodes. The combination of iodide and preparations of ammonia must be made cautiously, as iodide of nitrogen is formed, which explodes on the slightest touch. Indeed one ought to be very careful in ordering and compounding mixtures in which easily reducible substances enter—such as the chlorates, the hypophosphites, the nitrates, preparations of iodine or ammonia, chromic acid, glycerine, permanganate of potash, etc. If physicians would but remember the danger of explosions in preparing such compounds, they would less often put the lives of druggists and of their own patients in jeopardy.

The Antipyretic Action of the Alkaloids of Quebracho.—At the recent meeting of the French Association for the Advancement of Science at Blois, a paper was presented by Drs. Huchard and Eloy on this subject (*Le Progrès Médical*, October 4, 1884). There are many alkaloids of this drug, no less than six having been already isolated. Numerous experiments upon rabbits having demonstrated the antipyretic action of these alkaloids, the authors were led to make trial of them in the human subject. In a certain number of patients with typhoid fever, to whom quinine had been given without effect, a notable reduction of temperature was obtained by the hypodermic injection of the muriate of aspidospermine in doses of one and a half to three grains. This latter amount should never be exceeded. The authors noted especially the rapid reduction of temperature following the exhibition of these several alkaloids, and also remarked upon the changes occurring in the blood after their administration. The blood is changed in color in a way very similar to what occurs after poisoning by carbonic oxide.

Paralysis Caused by the Use of Crutches.—Dr. Vinay reports the case of a man, sixty-three years of age, who suffered from paralysis of the extensors of the forearms and of the long supinators following upon the use of crutches. The crutches were of very rude construction and had no supports for the hands. All the affected muscles, with the exception of the right triceps, reacted to the faradic current. A treatment by means of sulphur baths and electricity was instituted, and at the end of a month all the muscles were restored to their normal function, except the right triceps. The use of the poorly made crutches was, of course, abandoned. The author believes that paralysis of the triceps from this cause is of much more frequent occurrence than is generally supposed. He advises a treatment of this condition by the faradic current, friction, and sulphur baths, and removal of the exciting cause.—*Deutsche Medicinal Zeitung*, No. 77, 1884.

Syphilitic Arteritis.—At the meeting at Blois of the French Association for the Advancement of Science, Dr. Leudet related a case of syphilitic arteritis, accompanied by cerebral symptoms, occurring four years after the appearance of the initial sore. The superficial temporal arteries of both sides became cord-like, and the pulsations ceased in them. The cerebral symptoms, pain and loss of memory, occurring at the same time indicated a concomitant lesion of the brain. Under the influence of iodide of potassium all these troubles subsided, the arteries lost their indurated feel, the pulsations returned, and the cerebral symptoms gradually passed away. The author thought this case was important as showing the curability both of syphilitic arteritis and of cerebral syphilis.—*Lyon Médical*, October 5, 1884.

Biliary Calculus Passed by the Rectum.—Drs. Secrétan and Largmer relate the case of a man who suffered from frequent attacks of hepatic colic. These attacks ceased for the time after the expulsion of a lumbricoid worm by the mouth. But they soon recurred, and were accompanied by violent nervous crises, acute mania, left hemiplegia, and loss of the intellectual faculties, especially of the memory. Three months later these nervous symptoms suddenly ceased upon the expulsion by the anus of a large biliary calculus, nearly three inches in length by an inch and a half in thickness. The patient had never presented any symptoms of intestinal obstruction, and the reporters believed that a fistula had been established between the gall-bladder and the colon.—*Revue de Chirurgie*, October 10, 1884.

The Mechanism of Rotation of the Forearm.—Heiberg is of the opinion that in rotation of the hand the radius does not simply turn around the ulna, but that both radius and ulna rotate around an axis lying between the two. Dr. v. Meyer agrees with Heiberg that this may occur in certain cases, but regards it as occurring only exceptionally, and in cases in which the ligaments of the elbow are stretched to a very considerable extent. He concludes, therefore, that this rotatory movement of the ulna is not normal but is due to a partial subluxation. —*Centralblatt für Chirurgie*, No. 38, 1884.

A Prepuce Dilator for the Treatment of Phimosis without Operation.—Dr. Richmond writes in the *Medical Press*, October 1, 1884, concerning a new instrument which he has devised for the treatment of phimosis by gradual stretching. He says that the only method of treating phimosis, in common practice, is by operation. There are, however, a great many patients suffering from this malady who absolutely refuse to undergo any operation for its relief. Numbers of cases are constantly presenting themselves of men considerably advanced in years who have never been able to get their foreskins back, and have consequently suffered continually from discharges attributable solely to the irritation attendant on this condition. Yet many such patients will rather pass their lives with the inconvenience and risk which this state of things involves than submit to the knife. There can, however, be only one other possible means of treating phimosis, and that is by stretching the prepuce. But this method appears to be very seldom put into practice, for when it is tried it generally results in failure. I can see no reason, however, why the skin and mucous membrane surrounding the glans penis should not be as freely dilatable as in other parts of the body. The reason of the failure, I take it, is simply that no proper instrument has been invented for the purpose. Extemporized instruments, such as dressing forceps, aneurism needles, or blunted hooks, are painful and inadequate dilators. An instrument proper for the purpose should possess blades which could be introduced separately; the blades must be of suitable size and shape to suit the case; and it should be possible to open them parallel to one another or at any angle. The instrument which I have devised for the purpose consists of two rods, connected together by means of two long screws. At one extremity they are bent inward, and fixed to two blades. These blades can be removed, and may be of any size and shape. The rod is of tuning-fork shape, with a screw-nut sliding in the groove between the two branches of the fork. Through the nut is passed a long screw, the end

of which is received into a cup working on a hinge-joint attached to a cylinder, which slides along the bar. The screw-end may be detached from the socket by depressing a little spring. The blades are passed separately down between the foreskin and glans. Very small blades are used at first, and they are, of course, previously oiled to facilitate their passage. They are then attached to the rods, which are united by fixing the end of the screw into the cup-joint. Gradual extension can then be applied by turning the nuts. Since there is a joint at the cylinder, the blades may be opened parallel to one another or at any angle, and, in fact, the relative position of the blades may be altered in any direction. The idea is not to stretch the foreskin forcibly and at one sitting, but to dilate it gradually in the same manner as a stricture of the urethra is dilated, by repeatedly passing a catheter. If the instrument be used once or twice a week for about ten minutes at a time, the foreskin will in most cases go back in a month or six weeks. The larger blades are used to thoroughly stretch the tissues and complete the treatment. The foreskin may thus be dilated to any reasonable extent, and will, after a time, easily roll back over the corona. The instruments are made by Messrs. Arnold & Sons, of Smithfield, England.

An Autodidactic View of Diabetes.—In the *Gazette des Hôpitaux*, a physician has published a confrère's autobiography in so far as it relates to the careful observations of his own case, which was one of pronounced diabetes mellitus. The physician in question, having kept an eye on himself for many years, finally decided that glycosuria was a symptom of active and chronic hepatic congestion dependent upon gout. Like the latter, it should be treated by regulating the diet and not by the exhibition of useless drugs. He believes in white meat, eggs ,fish, chicory, spinach, artichokes, and lettuce. Absolute abstention from fruits, sweets, farinaceous foods, as well as coffee and all alcoholic beverages, is insisted upon.

Peritonitis Resulting from Diseases of the Vermiform Appendix.—Professor With, dealing with this subject before the International Medical Congress, said that the inflammation of the right iliac fossa, known by the name of perityphlitis, very often began in ulceration and perforation of the vermiform appendix. Peritonitis of this origin was called appendicular peritonitis, and was met with under three forms or conditions, generally well marked; as adhesive appendicular peritonitis (before perforation), and appendicular peritonitis, local or general (after perforation). As regarded treatment, the chief indication was to give the intestinal canal as complete rest as possible. To this end, sufficiently large doses of opium and morphia should be used, as well as complete abstention from laxatives and enematas, kept up for a period of twenty-four hours, if that were thought necessary. By means of this treatment, the indication for surgical interference underwent a considerable restriction.

Aseptol.—A phenol compound, termed orthoxyphenylsulphurous acid, has been recently introduced into therapeutics under the name of "aseptol," this title having been given to it on account of its remarkable germicide qualities, which excel those of carbolic and salicylic acids. Aseptol is an amber-colored fluid, of a density of 1,400; it has a slight odor, but is more pleasant to the smell and is less poisonous than carbolic acid. Last November, Drs. Leroy and Van den Shrieck, of Antwerp, studied the therapeutic applications of aseptol, and reported most satisfactory results as an antiseptic. It has the following advantages over antiseptics in common use: 1. It is very soluble in water. 2. It is very slightly caustic. 3. It is free from irritative qualities, and may be applied for a long time to the skin, the eyes, the bladder, etc. 4. Finally, its slight toxicity, which permits its use internally in considerable doses, and also the application of concentrated solutions in diphtheritic pharyngitis and laryngitis.—*La France Médicale.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 22, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.

Bell's Law Discovered by Magendie.—Professor Chapman says the credit of demonstrating the functions of the anterior and posterior roots of the spinal nerves belongs to Magendie, and not to Sir Charles Bell. When Magendie, in 1821, published the correct idea, Bell collected and destroyed, as he thought, the whole edition of his own pamphlet, printed in 1811, which advanced the idea that the posterior roots are trophic only, and quickly published another containing the true idea. Professor Chapman has seen a copy of Bell's treatise of 1811 which escaped destruction, and is now owned by the celebrated Richard Owen.

Gonorrhœa and Chordee.—Troublesome gonorhœal cases do not fail to occur except in the experience of those who are in the possession of unfailing remedies. A retired army surgeon, without apparently expecting such good results, ordered for an officer, some fifteen years ago, who was just about to present himself for duty, but who was suffering from gonorrhœa associated with an intense chordee at night, the following two preparations: aquæ, ʒ vij., mucilago acaciæ, ʒ j., ext. belladonnæ, gr. xx., and zinci sulph., gr. xx. A teaspoonful injected frequently. The other is an external application consisting of unguenti spermaceti ʒ iv., unguenti hydrarg., ʒ iv., ext. belladonnæ, gr. x., ext. opii, gr. x., to be smeared freely along the perineum and around the crura penis at night. "Complete cure" occurred within a week. The following injection for gonorrhœa is also recommended. It is claimed to be superior to any other single injection: ℞. Pulv. iodoform, 20; acidi carbolici, 10; glycerini, 80; aquæ destillatæ, 200.

Heart Beats.—Dr. N. B. Richardson, of London, says he was recently able to convey a considerable amount of conviction to an intelligent scholar by a simple experiment. The scholar was singing the praises of the "ruddy bumper," and saying he could not get through the day without it, when Dr. Richardson said to him: "'Will you be good enough to feel my pulse as I stand here?' He did so. I said, 'Count it carefully; what does it say?' 'Your pulse says 74.' I then sat down in a chair, and asked him to count it again. He did so, and said, 'Your pulse has gone down to 70.' I then lay down on the lounge, and said: 'Will you take it again?' He replied: 'Why, it is only 64; what an extraordinary thing!' I then said: 'When you lie down at night, that is the way nature gives your heart rest. You know nothing about it, but that beating organ is resting to that extent; and if you reckon it up it is a great deal of rest, because in lying down the heart is doing ten strokes less a minute. Multiply that by sixty, and it is six hundred; multiply it by eight hours, and within a fraction it is five thousand strokes different; and as the heart is throwing six ounces of blood at every

stroke, it makes a difference of thirty thousand ounces of lifting during the night. When I lie down at night without any alcohol, that is the rest my heart gets. But when you take your wine or grog you do not allow that rest, for the influence of alcohol is to increase the number of strokes, and instead of getting this rest, you put on something like fifteen thousand extra strokes, and the result is you rise up very seedy and unfit for the next day's work till you have taken a little more of the "ruddy bumper," which you say is the soul of man below.'"—*Gaillard's Journal.*

THE TREATMENT OF STAMMERING.—A correspondent in the *London Lancet* of September 27th writes that anyone may be cured of stammering by simply making an audible note in expiration before each word. Stammerers can sing as easily as other persons. Jacky Broster, of Chester, who made a large fortune by curing stammering, simply made his pupils say *h e r* before each word beginning with a consonant.

THE PECUNIARY VALUE OF ENTEROTOMY.—Dr. Sutton, of Pittsburg, having performed enterotomy on the wife of a wealthy resident of that city, removing four inches of intestine, was encouraged, by the fact of her complete recovery, to send in a bill of $1,000 for the operation and twenty-two days of attendance in the after-treatment. Each member of the jury, who finally adjudicated the matter, wrote on a slip what he thought would be a proper fee, and the sum total of the amounts thus voted, divided by twelve, was agreed upon as the verdict. The dividend was $330. One of the jurors thought about $10 would be a fair price, and another was willing to allow $30.—*Age.*

LATA OR MIRYACHIT.—In Java, according to the *British Medical Journal*, miryachit is known by the name of lata. The person affected with it is compelled to imitate everything he sees or hears. Our contemporary mentions an amusing case in which an Irish butler who was familiar with the symptoms of the disease took advantage of his knowledge to secure a glass of much-coveted wine: A doctor dined with a friend, with whom he discussed the peculiarities of the disease. The host pushed forward a bottle with the request to "try that, doctor; it's ten years old." The doctor took a stiff glass, and, smacking his lips, pronounced it "tip-top." Suddenly Barney, who had been present during the conversation, seized a glass and, filling it to the brim, drank it off, smacked his lips and pronounced it "tip-top." "Confound you," shouted the infuriated host, "what do you mean, sir?" "Shure, sir," demurely replied Barney, "oi'm afeard oi'm afflicted wid the latha."

REGULATORY ALBUMINURIA.—Rosenbach defines regulatory albuminuria as an albuminuria in which the quantity and quality of the urine are normal (except in containing albumen), and in which there are present no products of inflammation, such as tube-casts or blood-corpuscles. In such cases the kidneys are for the time functionating more than they normally do, and the albuminuria arises from anomalies of the blood or of tissue-change, and not from any disease of the kidneys themselves. It is to be remembered that in these cases the blood may be either absolutely or relatively richer in albumen than is normally the case. In the first of these cases the blood holds absolutely more albumen in solution than normal, and this may be due to a great absorption of albuminates from the food, to the transfusion of blood, or to peptonuria and the absorption of large pus collections. In the second case, the blood contains relatively more albumen than normal—relatively, that is, to its power of combining albumen—and this arises from increased loss of water through the skin or intestine, from diminished supply of water to the system, or from diminished functionating power in the white blood-corpuscles. In both these cases the excretory organs strive to reduce the albuminous concentration of the blood to the normal level, and hence the regulatory albuminuria. Rosenbach holds that the only characteristics of nephritis in its strictest sense are white (and the so-called "fatty") blood-corpuscles, and the tube-casts which are formed out of these corpuscles. He holds the hyaline corpuscles only as an indication of the presence of albumen, since, as is well known, they often occur when there can be no question of renal lesion. The red blood-corpuscles are only indications that the process possesses considerable acuteness.—*Zeitschrift für Klinische Medizin.*

THE MILK OF PREGNANT COWS UNFIT FOR INFANTS.—Dr. Ernest Mammen, of Bloomington, Ill., expresses an opinion below which is important if true, but which will be received with some incredulity. He says: "I have read with much interest the articles by Drs. Binnie and Vidal in recent issues of THE RECORD (September 13th and October 25th), and I heartily agree with these writers in their advocacy of cow's milk, fresh and pure, as the best substitute for mother's milk. But there is one factor which, in my experience, is often productive of harm that neither of them has mentioned. *The milk of the pregnant cow is unfit for consumption by the human infant.* This fact is too often overlooked, when by careful investigation the disturbance of stomach and bowels in cases of infantile diarrhœa could be traced to the use of milk. Where mixed milk is used the danger is that a proportion of it comes from pregnant cows. All hygienic care of the animals cannot make up for this condition of the milk, neither can the addition of sod. bicarb., common salt, lime-water, etc., destroy the deleterious principle, therefore my rule is to avoid it. I have recently had under personal observation a child weaned at six weeks, and put upon cow's milk. A good healthy animal was selected, and her milk, with the proper dilution and additions, agreed perfectly for three months, and that, too, during the summer. At the end of this time the cow was found with calf, and the infant's digestion was immediately disturbed. An obstinate diarrhœa set in, which could not be controlled until another cow, not pregnant, was substituted, when the child recovered and digestion was restored. I could cite other similiar instances, but the above illustrates the importance of this matter."

OZONE IN THE TREATMENT OF RHEUMATISM.—Dr. E. Brémond Fils has devised an apparatus for the application of vapor-baths of turpentine in cases of rheumatism, vesical troubles, lithiasis, etc. Ozone is evolved in the process, and is believed to be the active curative agent.

THE CHLOROFORM TREATMENT OF TAPEWORM.—We have received several communications upon the above subject. Dr. John H. Thompson, of this city writes: "Chloroform is *not* a dangerous remedy for tapeworm if properly used, but where any one gives a dose six times as large as necessary of a deadly drug then it may become dangerous. I have thirteen feet of tænia solium, with the head, that came from a patient March 27, 1870, after having suffered with it for fifteen years, and been to London and Paris to be treated for it. I, too, had tried pumpkin seeds, filix mas, and some other remedies, but succeeded with: ℞. Chloroformi, ʒj.; simple syrup, ℥j. M. One-third given at 7, 9, and 11 o'clock, followed at 12 o'clock by ol. ricini, ℥j., and the worm came at 1.30 P.M. from the happiest man I almost ever saw. I had caused my patient to fast absolutely for the twenty-four hours previous to taking my prescription, except allowing him to chew slippery elm bark. I have used the remedy in the same manner since with success." Dr. F. H. Enders, of Wailuku, Sandwich Islands, writes: "I have treated five cases of tapeworm at the Malulani Hospital successfully with the following: ℞. Chloroform, fl. ext., filix mas, ää ʒj.; emuls. ol. ricini, ℥iij. M. To be taken in the early morning. No food allowed until thorough action of the bowels. The entire worm was brought away in each case, with no unpleasant results." Dr. Charles H. French, of Waterbury, Conn., writes that he succeeded with the following: ℞. Olei tiglii, gtt. j.; chloroform, ʒj.; syr. glycyrrhiza, ℥j. M.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 29, 1884.

KOCH'S DEFENCE OF THE CHOLERA BACILLUS.

SOON after the announcement by Koch of his discovery of the specific microbe of Asiatic cholera, the now well-known comma-bacillus, there appeared in the medical press various doubts concerning the diagnostic importance of this newly fledged organism. We have kept our readers amply informed in regard to the various criticisms offered, as well as the protests made, against the acceptance of Koch's conclusions.

In the *Deutsche Medizinische Wochenschrift* of November 6, 1884, the distinguished German bacteriologist has just published a comprehensive reply to his critics. The most profound scepticism can hardly hold out longer against the new evidence adduced by Koch in support of his former claims, touching the relation of the comma-bacillus to Asiatic cholera.

Dr. E. C. Wendt, of this city, in an article published on page 589 of the present number of THE MEDICAL RECORD, alludes to these later investigations, and infers therefrom the necessity of scientific bacterioscopy. Without wishing to subscribe to all his suggestions, we must nevertheless admit that the profession of our country is not as familiar with modern bacteriological methods as could be wished. It may yet be shown that the practical utility of finding certain microbes in suspected cases has been overrated. But to deny them all diagnostic importance is to assume a voluntary blindness. From the accumulated evidences now before us, it would seem that the burden of proof rests with those who deny or dispute the validity of Koch's statements.

With especial reference to cholera, Koch shows, in the article referred to, that the comma-bacilli can be recognized as such only through the totality of their properties. Any single attribute, such as their peculiar shape, or a certain behavior toward stains, is not sufficiently characteristic to differentiate them from other and possibly quite harmless bacteria.

The alleged comma-bacillus ordinarily found in the mouth, and claimed by Lewis to be identical with the cholera microbe, has long ago been examined by Koch with negative results as to any discoverable relation between the two. Again, as regards the well-known allegations of Prior and Finkler, Koch shows that they employed faulty methods and, therefore, secured results devoid of significance. The specimens of their comma-bacillus which they submitted to him were found by Koch to contain four separate kinds of bacteria, but no cholera bacilli. For a detailed account of the essential differences between the true comma-bacillus and Prior's pseudo-bacillus we must refer to Koch's original paper. It is further stated by the indefatigable German scientist that in three cases of undoubted cholera morbus he found an abundance of various bacteria, but in no single instance any comma-bacilli. Moreover, Koch and his staff of collaborators have already examined the alvine evacuations in hundreds of cases of diarrhœa, dysentery, and other affections, as well as in health. Comma-bacilli were never found.

In a rapidly fatal case of arsenical poisoning, when the intestines and their contents showed naked-eye appearances closely resembling those of true cholera, no comma-bacilli could be detected.

And, finally, to crown all, cholera or fatal choleraic symptoms have been experimentally induced in various animals by the introduction of pure cultures into their intestines. Almost invariably the dead animals showed an abundance of the characteristic comma-bacilli in the intestinal tract. Koch reiterates, therefore, with added emphasis, his former assertions that the comma-bacillus is the specific microbe of Asiatic cholera, and occurs neither in health nor in any other disease. The sole point now on which the doubter can stand is that of denying the specific character of the inoculated disease. There does not seem, however, sufficient strength in this position to excuse either individuals, health boards, or governments from refusing to act upon the theory that Koch is right. And in this connection Dr. Wendt's suggestion, that we familiarize ourselves with scientific bacterioscopy, seems eminently proper, and should be strongly urged upon our authorities.

Koch's discovery is one of the grandest steps which have been taken in this century toward giving certainty to clinical medicine. And one must think almost with dismay of the tremendous collapse of scientific hypotheses and dogmatic teaching which its confirmation must produce. If it can be shown (and this yet remains to be done) that the bacillus is alone a sufficient cause of cholera, that it needs no prepared ground or special epidemic influence, the revolution of views necessitated will be indeed most extraordinary. But even should more extended observation show that the comma-bacillus can produce cholera only under peculiarly favorable conditions, its diagnostic significance would yet remain. And the early discovery of the microbe having all the weight of a pathognomonic symptom, would still give us a better chance of promptly suppressing an incipient epidemic than was ever before afforded us.

THE PRESENT STATUS OF THE QUESTION CONCERNING THE TREATMENT OF GOITRE.

ALTHOUGH goitre is by no means a frequent malady in our country, there is, nevertheless, among the foreign-born population enough of it to keep alive a certain interest in the disease, and especially as regards the means at our command for overcoming the annoyance of great disfigurement, if not the turning aside of grave danger. Hence neither physician nor surgeon can well afford to

ignore any positive advances in the therapy of this perplexing affection. In No. 244 of the *Sammlung Klinischer Vorträge*, October 8, 1884, Dr. P. Bruns, of Tübingen, publishes an instructive review of the subject in its most recent aspect, but more particularly from the point of view of the surgeon.

The author explains that it is a serious error, still prevalent in some quarters, to suppose that the steady growth and enlargement of a goitre constitute its chief dangers. A large experience has shown him that frequently the most formidable in volume are, at the same time, the most harmless tumors. It is the small-sized struma, and more particularly the substernal variety, that is potent for mischief, and often leads to a fatal issue. Death, indeed, happens unexpectedly in some cases where no violent symptoms of any kind had warned patient and physician of impending danger. The lightning-like rapidity of such an accident is explained by asphyxia and cardiac paralysis, following a sudden bending and collapse of the wind-pipe. Tracheotomy performed at the earliest possible opportunity has repeatedly failed to save life in cases of this class. All this would certainly show that persons afflicted with goitre are not to be dismissed with some consoling words in regard to the innocuousness of their tumors, but that their disease constitutes a legitimate cause for timely remedial interference.

The kind of treatment must necessarily vary with the nature of the thyroid swelling. Parenchymatous goitre should never be confounded in this respect with the cystic variety. In the former, treatment by iodides, both externally and internally, is always advisable before recourse is had to more energetic, but also more dangerous therapy. Experience has shown that iodides will prove of decided and lasting benefit only in those cases where marked effects quickly follow their first use.

Parenchymatous injections of iodine are at times very efficacious. But it is to be borne in mind that they are not without danger. Fatal consequences have resulted in more cases than one. The only radical measure of relief, however, consists in removal of the offending tumor. For all other operative procedures have been found to involve greater dangers and extend smaller chances of success than extirpation.

Cystic goitre is not amenable to treatment by the iodides. Puncture of the cystic cavities, followed by the injection of tincture of iodine, has been found to succeed in some cases. Billroth, indeed, claims twenty-nine cures out of a whole number of thirty-five cases treated in this way by him. From a careful study of a large number of cases of this class Bruns concludes that patients showing signs of disturbed laryngeal innervation should not be subjected to treatment by injection. As regards the operation of extirpation, the author pronounces it almost devoid of danger in uncomplicated benign struma. But he warns against complete removal of the thyroid body. For wherever and whenever this was done, a typical condition was sooner or later developed in the patient. It has been quite aptly termed by Kocher *cachexia strumipriva*. The most prominent symptoms of the latter consist in severe progressive cachexia, leading to a cretinoid condition of the sufferer, who soon shows a characteristic puffiness of the face. In addition there are alterations of the skin, general weakness, and decided awkwardness in all movements, without any diminution of muscular power, however, and finally, a pronounced loss of mental capacity.

From an analysis of this group of symptoms a remarkable resemblance to myxœdema becomes at once apparent. Add to this the fact that in myxœdema the thyroid body commonly atrophies, and the similitude seems still closer. Of course explanatory facts are entirely wanting to account for either the spontaneous development of myxœdema or the supervention of strumous cachexia after total extirpation of the thyroid. Various hypotheses have been advanced, but their discussion here would seem unprofitable.

As the final practical consequence of the most recent experience with struma it may be said that partial excision should always be practised. And in the individual case, before attempting operative interference, the surgeon should make sure that a portion of the gland can be left *in situ*. Total extirpation of the thyroid body, on the other hand, should never be performed. For it is physiologically unjustifiable, and should once for all be stricken from the list of permissible operations.

AN INTERNATIONAL HEALTH EXHIBITION IN NEW YORK.

The International Health Exhibition at London closed on October 30th. During its continuance from May to November there was a grand total of 4,167,000 visitors, or 27,000 per diem., and both from a financial and popular point of view it was one of the most successful exhibitions ever held in any country. This was due in a large measure to the concerts, restaurants, and various other "side-shows;" but despite all these the sanitary exhibits attracted much attention, and unquestionably a powerful impulse was given to sanitary studies and a knowledge of healthful living. The library of 7,000 volumes was very extensively used, lectures and conferences upon sanitary subjects were well attended, good work was done at the biological laboratory, while the very practical and objective teaching of the insanitary houses and similar exhibits could hardly fail to have impressed the most obtuse.

The exhibition conveys a lesson to Americans which we cannot believe will be long ignored. There should be a sanitary exhibition in this country, and in no part of the country more appropriately than in New York City.

We believe that America is ripe for such an enterprise. Sanitary problems have been studied, sanitary organizations established, and sanitary literature read more and more every year. The approach of the cholera has awakened a keen interest in the subject of municipal hygiene and maritime quarantine, and this interest will not subside until the danger is over or the epidemic has come and gone. The fact that the London exhibition was not only a popular success but that it might even be said that there is money in it will appeal with force to the minds of our money-getting countrymen. Apart from this there is economy in spreading abroad a knowledge of hygiene and inoculating the average mind with irrefragable proofs that healthfulness is worth working for and paying for. Let us have an International Hygienic Exhibition in the United States.

News of the Week.

What is the Correct Name for the New Local Anæsthetic?—Dr. D. K. Shute, of Washington, writes: "It strikes me that the correct, technical name for this drug is 'chloride of cocaine.' In an editorial of The Record for November 8th, it is stated that 'cocaine unites easily with dilute acids to form crystallizable salts,' therefore, if it unites with dilute hydrochloric acid it forms a crystallizable salt, which crystallizable salt is a 'binary compound' and *not* a 'ternary' one. Modern scientific works on chemistry make the characteristic termination of 'binary compounds' *-ide* and not *-ate*. 'Ternary compounds' have the characteristic termination *-ate*. A scientific chemist never speaks of the 'hydrochlorate of ammonia' as the result of the combination of hydrochloric acid (HCl) and ammonia (NH_3); but he calls the resulting compound chloride of ammonia or ammonium chloride (NH_3HCl) or, more properly, NH_4Cl). It is no more correct to say hydrochlorate of morphine, or hydrochlorate of cocaine, than it is to say hydrochlorate of ammonia. The result of the union of cocaine ($C_{17}H_{21}NO_4$) and hydrochloric acid (HCl) is, as stated above, a 'binary compound.' Therefore, to be correctly specified, this 'binary compound' should be written cocaine chloride ($C_{17}H_{22}NO_4Cl$). It is proper to say sulph*ate* or nitr*ate* of cocaine, because the union of nitric and sulphuric acids with cocaine forms 'ternary compounds.' I write these few lines in the hope that a drug having such brilliant properties may be dignified by being called by its proper scientific name, viz., cocaine chloride, chloride of cocaine, or cocainæ chloridum."

The Hospitals in New York Bay have been sadly in need of repair. The last Legislature stupidly refused to appropriate money for the purpose, but through the energy of the Health Officer and the liberality of the steamship companies, three thousand dollars was secured, and work is now in progress. Yellow fever cases go to Swinburne Island, small-pox and cholera to Hoffman Island.

Prior and Finkler *vs.* Koch.—While expressing as we have done elsewhere our great confidence in the superior skill and absolute trustworthiness of Koch, it is impossible to deny any credit to the entirely antagonistic views regarding the diagnostic and pathogenetic significance of the comma-bacillus expressed by Finkler and Prior. A correspondent of the *Allgemeine Medicinische Central-Zeitung* of November 8th, writes from Genoa under date of October 1st and states that Professor Finkler and Dr. Prior, of Bonn, have just finished their cholera studies at the Laboratory of the St. Andreas Hospital. He says: "The view maintaining the morphological similarity of the comma-bacillus and spirillum of Asiatic and sporadic cholera has been beyond question confirmed. So far as experiments here could determine, no difference in the cultures was observable. The various preparations of both kinds of bacilli show such a resemblance that no specialist could determine by microscopic examination the difference between Asiatic cholera and cholera nostras. By changes in methods of culture marked differences in the form and size of both kinds of bacilli may be produced. The pretended difference between the very thin bacilli of Asiatic cholera and the plump bacilli of cholera nostras is entirely artificial and not of the slightest importance."

These statements are utterly at variance with the recent announcement of Koch. We can only say at present that Koch is an investigator of long experience and established repute. Finkler and Prior are new in the field, and, furthermore, the report above quoted is anonymous and unofficial.

Notes on the Use of Cocaine.—The Baltimore Surgeons have been using cocaine extensively in eye and venereal diseases. The reports are as enthusiastic as any published in this city. Dr. Michael found it very useful in opening buboes and cauterizing venereal sores.

Dr. E. E. Holt, of Portland, Me., reports successful application of cocaine in eye cases (*Boston Medical and Surgical Journal*). Dr. W. E. Ground, of Toledo, O., has also had uniform success with the drug.

In Vienna the drug is being more and more used. Recent reports upon it have been made by v. Schrötter, Störck, Königstein, and Jelinck. The solutions employed are stronger (ten to twenty per cent.) than those which have been found adequate here. England and France have as yet had little to say about it, but wherever used the reports are unanimous in its favor.

Mr. Vanderbilt's Gift.—The letter of Mr. William H. Vanderbilt, announcing his munificent gift of $500,000 to the College of Physicians and Surgeons has been made public. Mr. Vanderbilt says in his letter, which is dated October 17, 1884:

"The health, comfort, and lives of the whole community are so dependent upon skilled physicians that no profession requires more care in the preparation of its practitioners. Medicine needs a permanent home where the largest opportunities can be afforded for both theory and practice. It seems wiser and more practical to enlarge an existing institution, which already has great facilities, experience, and reputation, than to form a new one. I have therefore selected the College of Physicians and Surgeons because it is the oldest medical school in the State and of equal rank with any in the United States. I have decided to give the College $500,000, of which I have expended $200,000 in the purchase of 29 lots situated at Tenth Avenue and Fifty-ninth and Sixtieth Streets, the deed of which please find herewith; and in selecting this location I have consulted with your Treasurer, Dr. McLane. The other $300,000 please find inclosed my check for. The latter sum is to form a building fund for the erection thereon from time to time of suitable buildings for the college."

The Price of Quinine is now about one dollar an ounce, but some druggists continue to charge at the rate of three or four dollars.

The Cholera in Paris was, at last reports, abating. A cable report to the *New York Times* says: The cholera has been handled very well in Paris. A large majority of the cases in the hospitals have been cured. The difficulty with the remainder has been either that the patient's system had already been ruined by alcohol or privation, or that the patient arrived at the hospital too

late. The latter is really the chief trouble everywhere. Dr. Chapman's treatment with ice-bags on the spine and Dr. Hayem's venous injections of a salt solution have both been successful. The old wrangle for and against Dr. Koch's theory continues, with the tendency to discredit it rather stronger than the contrary tendency.

The Value of the Hospital Collections.—In answer to a charge that the Hospital Saturday and Sunday collections have been an absolute detriment to the London hospitals, because of the diminished voluntary contributions at other times, the Secretary, Mr. Baker says: So far as Hospital Sunday in New York is concerned, it cannot be regarded otherwise than as a movement resulting in almost unmixed good. From the annual statements of the Associated Hospitals it is seen: 1, That during the past three years $201,651.44 was expended on the enlargement of accommodations; 2, that there has been an increase of $9,780.12 in the income from invested funds; 3, that there has been an increase of $43,036.72 from paying patients, at the same time that the number of free patients treated has increased from 6,698 in 1881 to 7,188 in 1883; while, 4, the increase of income from contributions toward current expenses other than derived from the Saturday and Sunday collection is represented by $22,774.84.

The Quack Triumphant.—Despite much talk and protestations, Professor Schweninger has begun his duties at the Charité Hospital, Berlin.

The Carnegie Laboratory.—We learn that Dr. Paul Grawitz has been unable to accept the position of Director of the Carnegie Laboratory and Professor of Pathological Anatomy at Bellevue Hospital Medical College.

Monument to the Late Professor Cohnheim.—The friends and pupils of the late Professor Cohnheim are arranging to collect funds for the purpose of erecting a monument to the memory of the deceased pathologist.

At the Recent Examinations for the Externat in the Paris hospitals there were 347 applicants, among whom were 6 women and 1 Turk.

Australia Refuses to Recognize American Medical Diplomas.—The Queensland Medical Board has passed a resolution refusing to register American diplomas, unless the professional knowledge of their holders is certified to by the passage of an examination at either of the Universities of Melbourne or Sydney. "It is much to be regretted," says the *Australian Medical Gazette*, "that there is not sufficient backbone in the other colonies to take a similar firm stand. The longest time required by the American colleges to be passed in study before the candidates are admitted for examination is three years, twelve months less than the shortest time required in the United Kingdom." It is to be regretted that Australians do not temper wisdom with their firmness and refuse registration only to colleges whose curriculum and requirements are below a good standard.

The Prudent Physicians of Italy.—Dr. A. Lagorio, writing from Chiavari to the *Chicago Medical Journal and Examiner*, relates some facts that may have a pertinent bearing here. He says: "At the first outbreak of the epidemic in Italy the Government made an earnest appeal to physicians to volunteer their work and skill in suppressing the disease and in treating its victims. This appeal had very little effect, for few responded; but through the presidents of the several medical societies of the State, our physicians assured the Government that they were willing to risk their lives as sanitarians and citizens; but, before doing so, they asked for a law making them equal to officers of the army, so that if the Government desired them to sacrifice their lives for the public health, it should assure them that their families would not have to suffer without receiving a suitable pension. The Government has not yet taken the matter in consideration." For physicians with a family and no money to leave for them such a proposition does not seem more than just. We shall certainly advocate the giving some help by the city or State to the families of poor physicians who die from epidemic disease contracted in discharge of duty.

A New Source of Lead-Poisoning.—Dr. Edson, of the Health Department of this city, has unearthed a new food adulteration quite startling in character, namely, the coloring of vermicelli with chrome yellow, a pigment containing lead, used for this purpose in lieu of eggs and saffron. Dr. Waller, chemist to the Department, analyzed a number of samples of vermicelli colored in this manner, and found in them an average of three grains of metallic lead to the ounce of food! Six manufacturers of the stuff were arrested and promptly fined at the Court of Special Sessions. The counsel defending them moved to have the cases dismissed because the Health Officers were unable to cite a single case where lead poisoning had been caused by vermicelli. The defence also brought witnesses who swore that they had eaten vermicelli colored with chrome yellow for long periods without injury. The publicity given the subject has, since the trial, brought to light one case of lead poisoning, the cause of which had been hitherto unexplained, in a person who had been in the habit of daily consuming a quantity of vermicelli purchased from a dealer whose stock, subsequently examined, was found to be colored with chrome yellow. Making our deductions from the amount of lead found in the vermicelli, we believe that other cases of poisoning must exist, caused by this practice, not recognized because practitioners have not had their attention called to this article of food as a possible source of lead-poisoning.

The Bismuth Test for Sugar.—Dr. D. Brown, of this city, writes: "In an editorial article in The Record for November 1st you call attention to: 'A New Bismuth Test for Sugar,' and credit its discovery and introduction to Almer and Nylander. Permit me to call your attention, to the fact that the late Professor Rand, of Jefferson Medical College, taught that test to his class in 1872; and you will also find it in his students' textbook, published the same year (see 'Elements of Chemistry,' pp. 373). Should he not therefore have priority?"

The Privacy of Hospital Records.—Dr. J. P. Fessenden, of Salem, sends us a reply to the Superintendent of St. Luke's Hospital, but we are unable to give further space to the controversy.

The Intelligent Interest in Medical Affairs displayed by the daily press is strikingly illustrated in the following description taken from a daily paper of this city: "For several years the physicians of this State have been considering the advisability of holding an annual meeting for the purpose of bringing together in consultation the leading members of the profession. The plan took form some time ago. This morning representatives from every section of the State assembled for the purpose of holding the first annual session." We are then told that Dr. Didman is President, Dr. Henton, Treasurer, and that Dr. Austin Flinn, Jr., was among the members present. More care is exercised in reporting glove fights.

Some Interesting Facts Regarding the Maintenance of Sick Seamen.—Seamen who may require surgical or medical attendance by reason of accident or disease, while employed on all classes of vessels, are at liberty to go either to a United States Marine Hospital, where the Government bears all the expense, or to call in the best outside surgical and medical attendance in the country, and the owners of the vessel are by law compelled to pay the bills. Therefore, if the Congressional appropriations for the maintenance of the Marine Hospital Service should give out, and the hospitals were closed up, all the sick and disabled sailor would have to do would be to put himself in charge of a first class doctor, who would have no difficulty in collecting his usual and legitimate fees from the vessel owner. "The repeal of the Marine Hospital tax," says *The Nautical Gazette*, "has opened a new field for impecunious physicians, and we may soon see our water-front graced by runners for doctors, just as runners solicit business for tow-boats, ship chandlery, etc." "Already two respectable physicians have called our attention to this condition of affairs, by requesting us to furnish them with copies of *The Nautical Gazette* in which was published a recent decision of a United States court upholding the constitutional right of a sick seaman to be cared for by a physician of his own choice, in a large seaport where the United States Marine Hospital had a corps of surgeons and one of the most perfect hospitals in the country."

Dr. W. M. Fuqua, of Hopkinsville, Ky., has been recently elected to the Chair of Anatomy in the Memphis Hospital Medical College.

Sir Spencer Wells on the Revival of Ovariotomy.—Sir Spencer Wells, in an address delivered at the opening of the Midland Medical Society on the revival of ovariotomy and its influence upon modern surgery, gives the following interesting *résumé* of the subject: "Before 1858, the operation, like all good things, had been of slow growth. One hundred years ago it was but a germ that might be descried in a lecture by John Hunter. Ten years later it was seed that fell from the hand of Bell. In little more than another decade it germinated as a living vitalizing reality in Kentucky. Sixty years ago it was transplanted to the land of its philosophical conception. In twenty years more we find it a sapling on English soil—growing slowly at first, and up to 1858 looking as if it might prove no more than a withering gourd. But by 1865 its root had struck firm, its stem stood erect, its branches were wide and strong, known and sought as a refuge by the sick and dying. That it was no withering gourd has been proved by all that the world has since seen. Thousands of perishing women have been rescued from death; many more thousands of years of human life, health, enjoyment, and usefulness have been given to the race; and to all future victims of a malady before inevitable in its fatality, it gives consolation, hope, and almost certainty of cure."

Unappreciated Opportunities for Young Physicians.—It is a somewhat curious fact that for a number of years there have been a considerable number of vacancies both in the Army and Navy Medical Departments[1] The Examining Boards meet again and again, but applicants do not come in sufficient numbers or with sufficient preparation to fill the vacant positions. It is difficult to understand why so many young men prefer long years of hard work and impecuniosity to the immediate receipt of a handsome salary and a good position.

Deaths from Cholera in New York in Past Epidemics.—Dr. John T. Nagle reports that in 1832 there were 3,513 deaths from cholera in this city, at the rate of 15.64 in every 1,000 persons. In 1849 there were 5,071 deaths, or 11.24 per cent. In 1854 there were 2,507 people died, or 3.95 per cent. In 1866 the deaths were 1,137, an average of 1.28 per cent. The epidemic of 1866 was of a virulent type, 583 persons who died having been attacked in the streets.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

The Question of Priority in the Use of Forceps in Breech Presentation. — Dr. H. T. Dunbar, of Union, N. Y., sends us the title-page of a pamphlet entitled "The Forceps in Breech Deliveries, with a Description of a New Instrument, by A. J. Miles, M.D., Professor of Diseases of Women and Children in the Cincinnati College of Medicine and Surgery." It is taken from the "Transactions of the Ohio State Medical Society for 1876." Dr. Miles antedates Dr. Fruitnight, therefore, by a year or more.

Reviews and Notices.

Daniel Gohl und Christian Kundmann. Zur Geschichte der Medicinal-Statistik. Von Dr. J. Graetzer. Pp. 155. Breslau: S. Schottlaender. 1884.

The author, Dr. Graetzer, gives a history of the origin of medical statistics, and an account of the lives and works of Gohl and Kundmann, the fathers of this science. The work is well printed and will be of much interest to statisticians and sanitarians.

Die Zuckerharnruhr mit einer ausführlichen Diätetik für Zuckerkranke. Von Univ. Med. Dr. Emerich Hertzka. No. 1, 8vo, pp. 181. Karlsbad und Nizza: Feller's *Diätetische Führer*.

This is the first of a series of "Diet Guides" which promise to be very useful. Dr. Hertzka has given us a very complete monograph on the diabetes mellitus, its etiology, symptomatology, progress, complications, and treatment. It will be a useful work to those who have these cases under treatment.

De la Répartition du Sang circulant dans l'Économie. Par le Docteur Emile Spehl. Thèse d'Agrégation, présentée à la Faculté de Médecine de Bruxelles. Bruxelles: A. N. Lebègue & Cie. 1883. The Distribution of the Circulating Blood in the Economy. 8vo, pp. 230.

This doctorate thesis represents a series of elaborate investigations into the distribution of the circulating blood in the brain, lungs, and muscles. The author has obtained some definite figures to represent the fact that the three organs referred to have more blood during functional activity than during rest. Perhaps his most interesting conclusion is that an environment of rarefied air draws the blood to the free surface of the lungs, but not of the skin.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual and Stated Meeting, November 24, 1884.

The adjourned annual meeting was called to order by the retiring President, Dr. S. Oakley Vander Poel, M.D., LL.D., who delivered the customary address, in which he reviewed the work done by the Society during the last year, its material and scientific prosperity, and introduced his successor in office.

Before resuming his place upon the benches he returned his heartfelt thanks to the Society for the uniform courtesy which had marked the conduct of the members toward him as their presiding officer, and suggested that more time be given to the discussion of the papers presented to the Society.

To do this the papers should not partake quite so much the character of an essay, but rather be directed to the elucidation of some particular point or method in the field of medicine or surgery. Let the papers be short and definite in purpose, and confined chiefly to controverted points, or such as require fuller demonstration. The same rules should regulate the debate. Nothing is more wearisome than a rambling debate where the narration of opinion and experience is so little related to the actual point under consideration. The remedy for this lies in the Society.

On motion by Dr. J. C. Peters, the Society extended to Dr. Vander Poel a vote of thanks for the faithful discharge of the duties of president during his term of office.

The Society then adjourned.

Stated Meeting.

The Stated Meeting was called to order by the President, Dr. Daniel Lewis, who delivered his inaugural address, in which he first expressed the deep and lasting obligations which the Society owed to his distinguished predecessor. He also expressed himself as profoundly grateful for the trust which the Society had bestowed upon him, and with its support would spare no effort to protect and advance its important interests.

Special reference was made to the question of increasing the membership of the Society, and also to the work of enforcing medical laws. The suit against the Eclectic Medical College is of such importance that no effort must be spared to win the case, as it is a diploma mill of such proportions as to almost rival the Buchanan College of Philadelphia.

The President then directed attention to the importance of having State Examining and Licensing Boards.

A very important change needed was a provision for revoking a license to practice.

Attention was then directed to the propriety of at once taking steps to secure a more commodious place for holding the meetings of the Society, as one must necessarily soon be secured on account of the recent good fortune of the College of Physicians and Surgeons.

At the close of the address, the President appointed the following

COMMITTEES FOR THE ENSUING YEAR.

Committee on Hygiene—Dr. Stephen Smith, Chairman; Drs. Alexander Hadden, E. H Janes, Cyrus Edson, Wm. L. Hardy.

Committee on Ethics—Dr. George A. Peters, Chairman; Drs. W. T. Alexander, Mark Blumenthal, C. C. Lee, E. Waitzfelder.

Committee on Prize Essays—Dr. F. R. Sturgis, Chairman; Drs. Frank P. Foster, W. R. Birdsall.

Auditing Committee.—Dr. P. Albert Morrow, Chairman; Dr. Gorham Bacon.

On motion by Dr. Vander Poel, that portion of the President's address which referred to change of place of holding the meetings was referred to the *Comitia Minora*.

After the report of the *Comitia Minora* Dr. Simon Baruch read a paper

ON THE THIRD STAGE OF LABOR,

in which he discussed at length the three plans of management—namely, expectancy, the Dublin, and Credé's method, and the method which occupies a middle ground, and which had been the most fruithful of good results.

Each plan was discussed in detail, with the citation of opinions of a large number of authorities, and also statistical information.

Dr. Baruch regarded the expectant plan as a retrograde step in the management of the third stage of labor.

He also believed that the superiority of Credé's method had been established by clinical experience and statistics. This method he regarded as a prophylactic against retention of the placenta and hemorrhage.

Under the third head the author of the paper discussed the physiological action of the uterus in removing the placenta, consisting of tonic contractions for its separation, and clonic contractions for its expulsion.

The modification which he advocated consisted mainly in the introduction into the vagina of two antiseptic fingers to retard too rapid expulsion of the placenta, to aid in removing it during a pain, and to secure removal of the membranes *without twisting*, and in the interval between pains.

Dr. Wm. M. Polk was invited to open the discussion, and said he did not understand how any man could wish to relegate Credé's method of expressing the placenta to the useless things to be discarded. He was heartily in accord with Dr. Baruch in his warning against discarding this method.

Dr. Baruch had advised that the chloroform be discontinued at the last period of the second stage, and to that view Dr. Polk took exception and remarked that he continued its use until the head of the child was expelled.

Dr. Polk also believed that no harm could come from twisting the membranes, and he thought that by so doing their delivery could be expedited.

Dr. R. A. Murray thought that the method practised by most accoucheurs was that which took the place of Credé's method; namely, keeping one hand firmly upon the fundus of the uterus as the child was expelled, and with delivery following the uterus down and retaining it there until permanent contraction of the uterus had taken place. He believed that Credé's method was applicable chiefly in those cases where inertia of uterus existed and there was threatened hemorrhage from chloroform, powerless labors, instrumental interference, etc.

With regard to twisting the membranes, he regarded it as most important in delivering the placenta, and further, that it should be done during a pain. Aside from these two points, he agreed thoroughly with the author of the paper.

Dr. Fruitnight spoke of the efficiency of the modification of Credé's method, namely, guarding against too rapid expulsion of the placenta, but he practised twisting of the membranes and believed it was advantageous to do so. Although the placenta might be retained within the uterus for several hours without doing harm, yet he regarded it as a foreign body and one which should be removed as soon as practicable.

Dr. Irwin said, concerning the practice of the Dublin school, that while the general sense might be in favor of the expectant method, yet interference was not precluded, as active as might be necessary. He thought the Dublin school could not be spoken of as either an interfering or an expectant school, but one which acts with due knowledge of the case in hand. The English school advocated less interference than did the Dublin school probably. With regard to twisting the membranes he thought there could be no doubt concerning the propriety of the procedure; pulling on the membranes was certainly objectionable.

Dr. Malcolm McLean spoke concerning the necessity of inspecting the placenta after it had been delivered.

Dr. Baruch said that he withheld the chloroform only at the very last moment of the second stage of labor. He objected to twisting the membranes because it encouraged pulling upon them. He objected to downward pressure under the circumstances mentioned by Dr. Murray, because it had been claimed that the Dublin method might produce inversion of the uterus. He therefore would not depend upon Credé's method in uterine inertia from chloroform, etc. In general he thought we should be guided less by individual experience than by the results in well-recorded cases in large numbers carefully watched.

Dr. Douglas, Treasurer, directed attention to the fact that he was prepared to supply the members with copies of

THE TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE

at *one dollar* a copy.

Dr. Piffard offered the following resolutions, which were adopted:

REGISTER OF MEMBERS.

Resolved, That a committee of three be appointed by the President to prepare a register of the members of this Society, to be entitled, "The Register of the Medical Society of the County of New York;" and to print the same and distribute it to members without charge, said Register to contain the names of active members, together with their addresses and office hours.

Resolved, That the *Comitia Minora* be requested to make the necessary appropriations to carry the above resolution into effect.

The Society then adjourned.

THE PRACTITIONER'S SOCIETY OF NEW YORK.

Stated Meeting, November 7, 1884.

A. B. Ball, M.D., President, in the Chair.

Dr. George F. Shrady read a paper (see p. 591) on

CASES OF STRANGULATED HERNIA, WITH REMARKS ON TREATMENT.

Dr. A. C. Post asked Dr. Shrady if he stated that in several of the cases reported no hernial tumor existed before the symptoms of strangulation developed.

Dr. Shrady replied that no tumor had been reported by patients in two cases until strangulation occurred, one of the patients being about twenty, and the other about forty years of age. It was quite evident that a small hernia had existed in the latter case, and had been overlooked by the patient. The other case was clearly one of strangulated congenital hernia, the sac being the tunica vaginalis.

Dr. Post believed it to be a very rare occurrence that a hernia was strangulated when it first came down, except when it entered the tunica vaginalis. There were cases, usually in young men, in whom the tunica vaginalis had not yet closed, in which, from a violent strain, the intestine sometimes descended for the first time to the bottom of the scrotum and was strangulated. Some years ago, during one of his terms of attendance at the New York Hospital, a sailor was admitted, forty years of age, who, while making violent exertion at the capstan, felt something give way in the abdominal walls. When admitted to the hospital there was a large swelling of the scrotum with great tenderness on pressure, constipation, and vomiting. The case was specially interesting because it had been seen by Dr. Valentine Mott, who said he would stake his surgical reputation that it was not a case of hernia. The shape was so much like that of a swollen testicle that Dr. Mott was disposed to disregard the account given by the patient, and supposed that instead of straining himself he had been struck by the capstan bar, and that a traumatic orchitis had thereby developed. Dr. Post had investigated the case very thoroughly, and had made up his mind that it was one of strangulated hernia; but, if he remembered rightly, not one of the surgeons of the hospital, all of whom saw the case, agreed with him. One or two, however, expressed themselves doubtful, while the remainder agreed with Dr. Mott. Finally, consent was given to an exploratory operation, when Dr. Post cut down upon a strangulated hernia in a high state of inflammation, and the patient died from extension of the inflammation into the peritoneal cavity. The strangulation, however, was relieved. Since that time a number of similar cases had occurred in the practice of New York surgeons, but that one, he believed, was the first to which attention had been called. Dr. Knight, of New Haven, had met with a similar case.

With regard to the general remarks made by the author of the paper, he was disposed to agree with him, though not fully with regard to the subject of taxis. He thought taxis was often carried to an injurious extent, but he did not think it ought to be passed over so lightly as the author of the paper would seem to do, and especially that it should not be passed over without trying a change of position. In a case of Dr. Rogers, in which he had made arrangements to operate before a class of students, Dr. Post requested an opportunity to attempt to reduce the hernia by a change of the patient's position. He had the nurse stand on a bed and raise the patient's feet over his shoulders, and in that way the hernia was reduced and the operation spoiled. Dr. Post had succeeded in reducing the hernia in that manner in a number of instances. No violence was thus done, but the falling of the thoracic and abdominal contents toward the head pulled upon the hernia, which proved safer and more efficient than trying to push it into the abdominal cavity.

In a case which occurred during one of his terms of attendance in the New York Hospital, the patient had a scrotal hernia which was somewhat inflamed and very tender upon pressure. Before operating Dr. Post thought it expedient to apply leeches. Half a dozen leeches were applied in the early part of the afternoon, and, as he had to attend the funeral of a distinguished member of the profession, he intended to operate on his return, but by that time spontaneous reduction had taken place, produced by relaxation from local bleeding. In the main he agreed with Dr. Shrady, that a great deal of harm was done by violence in taxis; but on the whole he should think that it were better to make judicious attempts at taxis than to proceed at once to divide the stricture.

With regard to the operation, he believed that, as a rule, a successful operation for strangulated hernia did not prevent another descent—that is, the hernia required as much support from trusses as before the operation, and sometimes more, on account of greater relaxation of the ring. He thought it better in all cases to seek to produce a radical cure. In an interesting paper published by Mr. Banks, of Liverpool, the utility of that practice had been demonstrated. The sac was divided at its neck, dissected out, returned into the abdominal cavity, and the ring was closed as far as possible with silver-wire sutures, leaving room enough for the spermatic cord. He gave a number of cases in which no dangerous symptoms were caused by the closure of the ring, and in which there was either an absolute cure effected, or the size of the ring so much reduced that it was possible to retain the hernia in its reduced position by a moderate amount of pressure. Mr. Banks was in the habit of operating in cases of hernia not strangulated; in all cases in which the hernia could not be kept in place by a truss. In a certain proportion of cases he effected a radical cure, and in others the hernia could be kept well supported by a truss.

Dr. Post agreed with Dr. Shrady in the treatment of the omentum, namely, that in all cases in which it had been strangulated, or had existed in the sac for some time, it was better to excise it than to return it.

Dr. McBurney said that Dr. Shrady was to be congratulated on having had so many remarkable successes in a large variety of strangulated herniæ. He supposed the usual modern antiseptic precautions were observed.

Dr. Shrady replied that the wound was irrigated from time to time with the sublimate solution, but that the spray was not employed. He did not hesitate to expose the gut to the atmosphere, and in two instances the members of the house-staff were allowed to feel of the stricture before it was cut. In no case did peritonitis develop itself.

Dr. McBurney said there was one point in which he had been much interested, namely, the old method still used of employing taxis. Certain cases which had come under his observation had led him to regret that taxis was not more generally acknowledged to be a dangerous as well as a valuable procedure in cases of strangulated hernia. Under certain circumstances it could be used with safety, but as Dr. Shrady had already pointed out, it was capable of producing a great deal of injury. It ought to be more commonly understood that some of the so-called methods of inducing the return of the descended hernia into the abdominal cavity were practically useless, and the employment of such methods as cold, heat, or even of position, if it occupied much time, might prove very serious for the patient whose condition demanded a speedy operation. He thought it a serious question whether we had not gone sufficiently far with taxis when we had given ether and made gentle manipulation with the fingers in attempts to reduce the hernia.

Among a number of other cases in which taxis was believed to have done the patient harm were the following: A few years ago he saw a child in consultation in a neighboring town, a strangulated hernia having existed about twenty-four hours. Four or five physicians were present, two of whom took the ground that taxis was a very serious procedure in so young a child. They refused to give their consent to the administration of ether, and

thought taxis was entirely unjustifiable without it. One of the others would consent to taxis under ether, and the fourth supported Dr. McBurney in the recommendation of etherizing the patient, attempting taxis, and, failing, to proceed to operate. The child was not under the influence of the anæsthetic a minute before the hernia was reduced with the slightest manipulation.

About four years ago he saw a case in New Jersey which, as he learned after his arrival, was under the charge of two homœopathic physicians. The physicians refused to allow anything whatever to be done, saying the patient was too old to justify an attempt at taxis, it being a case of strangulated hernia, and an operation, they said, should not be thought of.

It seemed to him it would be very useful if positive rules could be given as to the kind and amount of taxis which should be employed in cases of strangulated hernia. He thought that the first important point to bear in mind was that taxis should not be attempted before etherizing the patient. By this means, he thought, we entirely relaxed muscular action in the abdominal walls and relieved all tension upon the strangulated parts, and then by inverting the patient the best conditions would exist for the return of the hernia. All local applications were intended, he believed, to reduce inflammation and congestion of the parts, but if it were intended to try to reduce the hernia by manipulation he thought the earlier it could be tried the better, and finding that it failed, an operation should be performed immediately.

With regard to the treatment of the sac, although his experience was slight he was inclined to agree in the view expressed by Dr. Post that the method so largely practised by English surgeons of late, of drawing together the pillars of the inguinal canal by suture after freeing the peritoneum, and thought it would be likely to result in permanent cure in many cases.

Dr. V. P. Gibney had been much interested in the remarks made with regard to taxis. For a number of years he had seen a large number of cases of hernia, and had effected reduction by taxis in many cases at all ages, and he was not now able to recall a single instance in which immediate or remote damage had been done by taxis as he employed it. It had been the custom at the Hospital for the Ruptured and Crippled to first try taxis, and that failing, to refer the patient to the consulting staff for operation. But taxis succeeded in nearly all cases. How much manipulation in attempts to reduce the hernia had been employed by physicians before the patients came to the hospital he was unable to say, but after their admission he and two assistants would try taxis, then give ether, or, if the patient were a child, chloroform, and attempt reduction again, placing the patient in different positions so as to favor the return of the hernial contents. Sometimes gentle and persistent taxis would be employed half an hour, and, failing, an anæsthetic would be administered, and usually the hernia would finally be reduced. Last year a child was brought to the hospital which was said to have been suffering from a strangulated hernia for twenty-four hours. There was some vomiting, a very tense tumor, and marked signs of strangulation. Dr. Gibney employed taxis for half an hour, then gave chloroform, and after another half-hour's manipulation succeeded in getting the tumor about two-thirds reduced, but not being able to produce any further effect, he directed the mother to take the child home and if the hernia caused any further trouble to call in a physician. She returned the next day and said that in carrying the child home the hernia disappeared. This was not a solitary experience.

Dr. Gibney was unable to understand how intelligent taxis was going to do the harm which it had been claimed that it would do. But he agreed with Dr. McBurney, that there ought to be some definite rules for the employment of taxis. If after taxis had been employed the surgeon should lose the case by an operation, there would be a natural tendency to attribute the bad result to the manipulations employed by the physician who first saw the case. He had seen a number of cases relieved by lifting the patient by the hips, and other changes in position. He supposed that when an anæsthetic was employed the beneficial result was brought about in the manner described by Dr. McBurney, both as to the action of ether and chloroform.

Dr. John A. Wyeth had been surprised at the number of successive successful operations for strangulated hernia reported by Dr. Shrady, especially as in many of those cases the condition had existed for so long a time as presumably to debar a good result. If he understood the histories correctly, in a majority of the cases strangulation had existed over twenty-four hours, and in some as long as three days, which was a very long period for strangulation to exist and still permit of recovery after an operation.

It had been Dr. Wyeth's practice to operate early. Since December 20, 1882, he had performed seven operations for strangulated hernia, all of the patients recovering. He believed that the success of the operations was due to the fact that they were performed early after strangulation had occurred. In some of the cases, however, he could wish to have seen the patients sooner. He believed that much of the danger of the operative procedure was due to the previous improper use of taxis. He regretted very much to hear so eminent an authority as Dr. Gibney express himself so favorably toward taxis, thus encouraging physicians, especially young men, to place reliance upon this procedure in cases of strangulated hernia. He doubted whether there was a surgeon present who had not met with cases in which the patients had been brought near the point of death from prolonged and indiscriminate use of taxis. No man ought to touch a strangulated hernia until the patient had been placed under the influence of ether. He himself, however, was loath to try taxis even after having anæsthetized the patient. He had never yet been able to reduce a hernia except by an operation. But then he had not pushed and bored the gut back as some would do. He knew of one case in which the hernia had been reduced within the sac, and it was afterward necessary to operate to relieve strangulation.

An operation for strangulation was as free from danger, when done under antiseptic precautions and early enough, as any major operation could be. There was one precaution which he took in performing the operation. The inguinal ring when cut into acted as a funnel for the conduction of fluids into the peritoneal cavity, and to prevent any accident arising from this cause he inserted his finger into the ring and thus obliterated it. The gut was thoroughly irrigated with the sublimate solution, then returned, and the finger placed on the ring and retained there until the completion of the operation. Two strong sutures were passed through the entire thickness of the edges of the wound, including the abdominal wound and sac in one mass, and a drainage-tube was inserted. He thought Dr. Shrady regarded the operation as being less difficult than it really was. Out of Dr. Wyeth's first three cases operated upon for strangulated hernia, two of the patients died, and it was not improbable that the difficulties of the operation and lack of experience had something to do with the fatal issue. In femoral hernia there was danger of injuring the obturator artery when derived from the epigastric. Femoral hernia occurred most frequently in females, and it was in females that we found this artery in every other case derived from the epigastric branch of the external iliac. In all of the cases which he had found in which death had resulted from hemorrhage into the peritoneal cavity from injury to this vessel, the accident occurred in women.

In his seven cases the strangulation had existed for periods varying from two to forty-eight hours. While the gut in one or two instances was mottled, yet the circulation was restored. In one case the condition of the gut was such that he would have exsected a part, had it

not been that the operation was performed by candle-light in a tenement house. The patient recovered.

Dr. J. W. Wright said with regard to taxis, that he had always entertained the opinion expressed by some of the speakers, that, as it was generally employed, it was a very dangerous procedure in strangulated hernia. He thought, however, that there was a way to employ taxis which was safe, or at least by which it was not made a very dangerous measure. Taking hold of the hernial tumor which was strangulated, and pressing it violently with all the strength of the hand, without using even the ordinary and necessary skill to get the hernia back, if possible, in the inverse order to that by which it had come out, was a very dangerous procedure. So impressed had he been with this idea that he had come to make it a law to himself never to attempt taxis in a hernia which had been strangulated for a long time, until the patient had been put under the influence of an anæsthetic, and then, if after one reasonable trial, not a very violent one at that, he did not succeed in reducing the hernia, he felt that the patient's chances of recovery were infinitely better if he proceeded at once to operate. With regard to the reduction of strangulated hernia by a change of position, alluded to by Professor Post, he considered it a very important point. He could recall two or three cases in which herniæ had been strangulated, and two or three attempts had been made at taxis by men who were supposed to have the requisite skill, and had failed, but the taxis had succeeded at the first trial when the patient's position was changed. In two cases which he recalled the reduction had been very easily accomplished by the operator standing with his feet upon the bed, spreading the patient's limbs, taking him by the knees, and lifting his body upon the body of the operator. It was not a very genteel position, especially if the patient were a female, but in the male he had known it to succeed very easily. One of these cases was that of an unrecognized strangulated femoral hernia which had occurred in connection with a double inguinal hernia. Both of the inguinal herniæ were down at the time, but neither of them was strangulated, and yet the patient had well-marked symptoms of strangulated hernia, and a very careful investigation revealed the presence of a very small femoral hernia which was irreducible by taxis in the recumbent position, but which was reduced by taxis when the patient's hips were elevated in the manner described, and with immediate relief of the symptoms.

With regard to what should be done at the operation. First, he did not regard the operation for the relief of a strangulated hernia a very simple affair, because he felt that every hernia was a hernia by itself, and the details of the operation for any given case could not be learned from books nor from lectures. Every hernia had certain peculiarities of its own. With regard to the treatment of the sac his impression was that the method described, of dissecting it out, and stitching the walls through and through, offered a much better support, and a much greater probability of curing the hernia than the operation which was commonly resorted to. That plan had been very clearly brought out by the gentleman to whom Dr. Post had referred, Dr. Banks, of Liverpool, who in performing the operation left the abdominal walls and peritoneal surfaces as smooth as possible, so as to guard against the formation of a new hernial pouch.

Dr. Post remarked that the urgency for an early operation was greater in small than in old or large herniæ, the reason for which was apparent.

Dr. R. F. Weir agreed with most of the speakers, that there was considerable risk attending taxis, but in connection with the question of change of position it would often be found that lateral motions would aid in the reduction of the hernia. In cases in which strangulation had existed for some time taxis had other risks than those simply pertaining to manipulation. The gut might be in such a condition that, on being thus reduced, circulation would not return and it would give rise to a fatal peritonitis. He had become so strongly impressed with this danger that he had made it a rule, when called to see a case of strangulated hernia which had existed for some time, not to be satisfied with reduction by taxis, but to operate and see what was the condition of the hernial contents before returning them to the abdominal cavity. It was to be taken for granted that a sufficient amount of taxis had already been made before the patient had been placed under the care of the surgeon.

He thought the treatment of the wound adopted by Mr. Banks, and referred to this evening, was attended by some risks, as in one case the patient died of what the house surgeons supposed to be peritonitis resulting from the operation, but, as the post-mortem showed, death took place from strangulation of a portion of gut in the narrowed ring. He believed other surgeons had had a similar experience with this method.

Dr. Shrady, in closing the discussion, said the paper was not intended to be an exhaustive one on the subject of hernia. He had been more particularly interested in the remarks made upon taxis, and he presumed that all who had referred to this point were of one accord. He thought it specially important that taxis should not be attempted seriously until after the patient was under ether, a point which he had already brought out in the paper. That being the case, no one should attempt taxis unless he was prepared to do herniotomy. Taxis was tried in all the cases reported in the paper after the patients were etherized, but unsuccessfully.

With reference to cutting off the sac and securing it to the abdominal ring, he had had one unfortunate experience. He thought that the method spoken of by Czerny, about five years ago, was very promising from a theoretical standpoint, and he tried it in one case of irreducible hernia in which there was great adhesion of the sac. He dissected out the sac, which was one of large size, cut it off, secured the stump in the external ring, and thought he had made a very nice operation until peritonitis developed, from which the patient died. Since then he had not meddled with the sac in that way, but compromised by sewing as high up in the neck of the sac as he could by strong ligatures, taking a stitch through the pillars of the ring, but leaving the sac in position. In four cases he was quite certain there had been entire obliteration of the sac. He had stated in the paper that the healing of the wound by granulations was not a disastrous accident, as thus the sac would become obliterated. Of course a little pouch would be left, but by a support the patient would be protected from further descent of the hernia.

The kind of taxis referred to by Dr. Gibney was skilled, and of a different nature from that usually practised, by which the patient was much harmed before he came under the care of the surgeon. He had often succeeded in reducing the strangulated gut by taxis, but always preferred to give ether before resorting to it. He believed that the method of changing the position of the patient by suspending him by the legs, as recommended by Dr. Post, was very often successful. Dr. Shrady always tried it in connection with the other accepted manipulations before resorting to herniotomy.

MODIFIED ELECTRODE.

Dr. Beverley Robinson presented a modification of Dr. Lincoln's electrode for use in the naso-pharynx. The original had a cup made of ebony, bone, or ivory, and in his hands had split and came near entering the air-passages of the patient. He had replaced this by a hard rubber cup, which, besides not being likely to break, became less rapidly hot; but it was liable to take fire, and also to become soft. Finally he had substituted an electrode protected by a layer of asbestos, which seemed to be open to none of the foregoing objections.

GENERAL TUBERCULOSIS.

Dr. V. P. Gibney, presented a specimen from a case of general tuberculosis, accompanied by the following history:

G. R——, aged three and a half months, came under observation one month before death. Parents moderately healthy, no history of hereditary tuberculosis being traced. The mother had had seven other children, three are living in fair health, the others were either still-born or had died when a few months old, one with convulsions, the others "wasting away." The child was a twin, the brother having died at the age of seven weeks. It was at birth of fair size, but had never thrived after the first few weeks, although nourished at the breast. The bowels were generally loose, the child having three or four passages a day. When it was first seen it was thin, but not emaciated. No signs of inherited syphilis were present. Nothing was found in the lungs but a few scattered râles. There was no vomiting.

The case was at first believed to be one of malnutrition, but treatment was without avail. The case grew steadily worse, and a slight febrile movement, somewhat irregular in its occurrence, was noted. The emaciation finally became extreme. The fontanelles were depressed; there was extreme nervous irritability, but never any convulsions. The bowels continued loose, and death occurred from a progressive asthenia. There was slight tympanites noted at times. Cough existed for two weeks preceding death. At the last examination of the lungs, about ten days before death, only the signs of diffuse bronchitis were found.

Brain was found normal. Right lung adherent through nearly its whole extent. A small sacculated pleurisy at its lower anterior border containing about an ounce of fluid. Both lungs studded with tubercles on the surface, and through their substance. A small cavity about the size of a pea near the root of right lung. Bronchial glands enlarged and cheesy. Heart normal. Liver studded with tubercles, as was also the spleen. This was about twice its usual size. Many tubercles found in the great omentum, but no lymph or pus. A few tubercles on the surface of the kidneys.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 20, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. A. C. POST exhibited a new hard-rubber syringe, so arranged that it could be opened at both ends for inspection of the pistons, and could be worked with a single hand.

THE PRESIDENT introduced Dr. W. C. Wile, of Connecticut, and Dr. M. F. Price, of San Francisco, ex-surgeon of the United States Army, and invited them to seats upon the platform.

THE SURGICAL MANAGEMENT OF RACHITIC DEFORMITIES OF THE LOWER EXTREMITIES.

DR. V. P. GIBNEY read a paper on the above subject in which he said, first, by the term surgical management he wished to convey the impression that mechanical appliances as well as cutting instruments are surgical means for effecting relief.

With reference to knock-knee, it was not every case that demanded surgical interference. Exaggerated cases have been known to recover spontaneously.

Dr. Gibney then referred to the definitions which had been given by different authors, as Macewen, of Glasgow, Little, of London, Poore, of New York, and others, and asked, Do any cases of true knock-knee recover spontaneously? It was his opinion that a fair proportion of the cases in the United States make a spontaneous recovery, and the statement was based upon the following reasons:

First, between the years 1871 and 1877, at the Hospital for the Ruptured and Crippled, he saw 252 cases in children under fourteen years of age suffering with knock-knee. The apparatus employed was theoretically inoperative, practically it seemed to be of some service. In nearly all the cases the limbs were restored to their normal position. The apparatus employed consisted of a pair of springs which supported the limbs, but which did not exert any force against the deformity.

Another reason for the belief in the spontaneous cure of knock-knee was the scarcity of adult cases in this city. Seldom does one see adults with this deformity walking on the streets of New York. He felt safe in asserting that the larger number of cases have occurred in children between three and eight years of age, in which osteotomy has been performed for the correction of the deformity of knock-knee.

With regard to bow-leg, he was sure that many general practitioners could refer to children whose limbs were bowed during early childhood, but which ultimately became straight. Of the 1,005 children with this deformity seen at the Hospital for the Ruptured and Crippled, 927 were in children under fourteen years of age. Only three cases were seen in adults, and only five occurred between the ages of fourteen and twenty years. In the 927 patients the age ranged from two to four years. Dr. Gibney believed that he would be correct in the statement that the great majority of the patients operated upon in this city for bow-legs, had been under seven years of age.

The author of the paper then discussed the following questions: First, What cases can be safely left to nature? Of knock-knee and bow-leg he would say that children under two years of age should not be subjected to operation unless the deformity be very exaggerated; also that children under three years of age, with a moderate degree of deformity, could safely be left to nature.

Knock-knee and bow-leg for the most part are due to rickets, and therefore considerable was to be expected from medicinal measures toward effecting a cure. Dr. Gibney then spoke of climatic influences, and the use of phosphates of lime and soda in the treatment of rickets, and expressed the opinion that the latter were satisfactory only as they improved digestion and general nutrition.

In what cases should manual force and retentive splints be resorted to? In the first place, in those patients whose parents are unable to buy an apparatus or too improvident to give any attention to the correction and cure of the deformity. Second, when one has but little time to effect a cure. Third, where the bones will yield readily to such force, the other conditions being present. Dr. Gibney quoted upon this point the conclusions reached by Macewen, that it may be safely concluded that *brisement forcé* has served its time, and cannot be practised in the presence of the more exact methods of the present day. From his own experience and from the drift of sentiment, he felt well assured that Macewen's conclusions would be more strongly supported at the close of 1884 than they were at the end of 1883 in the treatment of genu valgum.

With reference to apparatus, Little, of London, was an advocate of mechanical appliances, while Macewen, of Glasgow, was opposed to their use.

So far as bow-legs are concerned, Dr. Gibney had been guided in their treatment by the principle, that if the bones could be sprung into position by the use of a moderate amount of force, a retentive apparatus, consisting of springs, could be applied with benefit. If the femur is curved and the inner condyle unusually long in a case of knock-knee, he tests with his hands the ligaments of the knee and the femoral curve, and is guided by the result in his selection of cases for apparatus. The age beyond which he found this test failing was four and five years.

All springs now in use are constructed upon one principle, namely, force brought to bear against the convexity of the curve at its apex. Dr. Little, of London, applies continuous pressure; Dr. Shaffer, of New York, employs momentary pressure; Dr. Poore, of New York,

reports that about thirty per cent. of the cases of genu valgum are cured by mechanical appliances.

Osteoclasis.—This operation has not become popular in this country, notwithstanding its popularity in France.

Osteotomy.—This operation has become applicable to nearly all rachitic deformities of the extremities. For the details of the operation Dr. Gibney referred to Dr. Macewen's writings. He simply mentioned what Dr. Macewen had stated at the International Medical Congress at Copenhagen, that in none of his cases had death occurred due to the operation. The author of the paper then spoke of the accidents which might occur in osteotomy, especially the hemorrhage. In speaking of the applicability of osteotomy he made the positive statement that he had never seen an anterior tibial curve which had been corrected by apparatus of any kind.

In nine linear osteotomies and two cuneiform osteotomies which he had performed within the last year, in none of the cases had the temperature of the patient risen above two degrees Fahrenheit. In one case of supracondyloid osteotomy a result occurred which he believed to be unique—namely, paralysis of the external perineal nerve, due to injury by the callus.

From his experience in the performance of osteotomy Dr. Gibney had learned the following lessons:

First.—Exaggerate the correction of the deformity.

Second.—Examine the limb at the end of a week and ascertain whether the amount of the correction gained is the amount desired.

Third.—Do not hesitate to refracture by manual force, if necessary.

Fourth.—With strict attention to details in operating and in the use of good plaster-of-Paris splints, cases can be treated in dispensaries nearly as well as in hospitals.

Fifth.—In dispensary cases do all the operating you propose at one sitting.

Further, Dr. Gibney remarked that he had employed and believed that Listerism possessed advantages, especially with reference to cleanliness. Support of the limb for three months after the operation, by some form of splint, was not too long.

The President invited Dr. Joseph D. Bryant to open the discussion, who said, with reference to the cases which can be safely left to nature, that he agreed with Dr. Gibney entirely on the point that in a large number of cases occurring in children the patients would, if permitted to go untreated, ultimately make a complete recovery.

The cases, however, which can be safely left to nature involved a broader question, namely, the cause of bow-leg and knock-knee. The exact cause of bow-leg, it was true, was not yet thoroughly determined. The weight of the body had been regarded as one of the influences, and probably had much to do with the production of the deformity. Muscular contraction had been said to be one of the causes, although there was some doubt on this point. The position of the child also, as the majority of these children sit cross-legged, had been alleged to be one of the causes.

If the weight of the body in walking and muscular contraction were among the physical causes of bow-leg, then it was true that something could be done to correct the deformity or prevent its complete development, and the fact that many whom we see upon our streets do grow up with bow-legs gives rise to the question, Can we safely leave any of them to nature?

So far as medication and hygiene were concerned in the treatment of rachitic deformities, the question was probably well settled, and he had nothing to add to what had already been stated by the author of the paper.

With reference to the application of manual force, the rule which he had adopted was this: If in connection with bow-legs he found that by applying force he was able to spring the bones into their normal position, he had endeavored to rectify the deformity by making forcible pressure upon the convexity of the curve two or three times a week.

Dr. Bryant then referred to a case of exaggerated anterior curve of the tibia, which he cured in this manner: He placed the patient, a boy, under the influence of an anæsthetic, then exerted as much force as he possibly could, without fracturing the bone, in the direction of reducing the curve, applied a simple retentive splint, repeated this operation a number of times, and the result was a complete cure.

He regarded this method of treatment as preferable to osteotomy in all cases of this kind, aside from the fact that in osteotomy we have a compound lesion.

With regard to apparatus, he believed that every case, in which the deformity could be corrected by manual force, was a proper case for the use of some form of retentive apparatus. He was rather inclined to favor the use of springs which should not exert very much force, only sufficient to correct the deformity without producing any injury of the soft parts.

With reference to osteoclasis, so far as his knowledge extended, it had been used in this city very little indeed. He certainly never would resort to it where pressure was to be brought at an angle involving the joint, as in genu-valgum. The danger to the ligaments and to the synovial membrane, and the danger of crushing the soft tissue of the head of the tibia, were reasons for not resorting to it in preference to osteotomy. However, in marked tibial or femoral curve, where the force could be brought directly upon it without interfering with the epiphyseal junction, there might be no very great objection to it, except in the anterior tibial curve.

With reference to osteotomy, Dr. Bryant regarded it as one of the important advances in surgery in the present century, especially when combined with antisepsis. He had not seen any ill results in his cases in Bellevue Hospital, and had not seen a drop of pus associated with his operations. Dr. Bryant then referred to an aggravated case of antero-lateral curve of the tibia, due to a badly united fracture. He operated upon the patient in Bellevue Hospital, and found the bone so hard that the chisels were broken in attempting to divide it. The wound was dressed antiseptically, and within eight months after the operation the patient went out entirely cured. He referred to the case merely as an illustration of the beneficial effects produced by antiseptic dressings.

The oldest patient upon whom he had performed osteotomy was sixteen years of age. He performed the supra-condyloid operation. In that case there was a rise of temperature on the third or fourth day, but this quickly subsided, and no further rise occurred. So far he had not met with any accidents.

With reference to the applicability of the operation, he should limit it to all those cases where consolidation of the bone has taken place. He thought the general importance of the subject was sufficient to engage the attention of all surgeons.

Dr. C. T. Poore thought that unless the real pathological condition was taken into consideration none of these deformities could be treated intelligently. In one class of cases the deformity was not due to bone lesion. When it was due to bone lesion he thought it was always due to rachitis, leaving out traumatic cases. If that was true the question arose, What shall be the mode of treatment? In the early stages of rachitis the bone can be bent and the deformity corrected, but if knock-knee is due to enlargement of the internal condyle, or bending of the femur, etc., or if the bones have become hardened, they cannot be bent, and, therefore, the deformity cannot be corrected in this way.

He had no personal knowledge of spontaneous cure occurring in these cases of deformity of true bony origin. Dr. Gibney had stated that he had seen such cases, and the statement was to be accepted without question; but Dr. Poore did not think that they were very common.

The fact that we did not see on our streets many cases

of knock-knee in adults he thought was due to the fact that there was not so much of rickets in this country as in some other countries.

He thought that the deformity could be cured by mechanical treatment if taken in time, and splints were properly applied. However, if after a time no further improvement could be secured, there was nothing further to be gained by the use of splints.

With reference to the date at which bones became hard, each case must be judged by itself. One child may have rachitis and recover with hard bone at three or four years of age, while in another case the bones will not become hard until eight or nine years of age. He regarded it simply as a question of nutrition. After the bones have become hard, he thought that the deformity could be corrected only by operation.

With regard to osteotomy, he had nothing to add to what had been said. In those cases in which hemorrhage had occurred, except one in which the femoral artery was injured by a spicula of bone, the accident was due to causes which could have been prevented. In his own cases he had not kept his patients in bed more than five weeks. He removed the plaster-of-Paris dressings at the end of four weeks, and probably the patient was out of bed within a few days, and he had not had any recurrence of the deformity, nor did he know of any in which the deformity recurred after the patients left his charge.

With regard to osteoclasis, he thought that it was far better than manual force, for the fracture could be made at any point desired, provided that it was done at a sufficient distance from the malleoli. He had never produced a fracture less than three inches above the malleoli, and he had never seen an accident of any kind from osteoclasis, nor had he ever failed to correct the deformity by resorting to this method of treatment. He had not had any experience in bending bones by means of mechanical appliances.

With regard to osteotomy for bow-legs, it seemed to him that in all cases of long curves the osteoclast could be used with advantage; the short angular curves are better treated by osteotomy. In his operations he had not resorted to Listerism strictly speaking, nor did he dress the wounds according to Macewen's plan.

Dr. M. H. Henry had not, within the last three years, performed osteotomy, but he had seen the operation performed by his friends, and he was in perfect accord with the statement which had been made by Dr. Gibney in his excellent paper. For many years, while in charge of the Immigrants' Hospital, he saw a large number of children of foreign birth. There were no colored children, and there were but few cases of deformity among the Italian children. He mentioned these facts because they served to account for the frequency of the disease as it exists among the children of foreign parents. The children were mainly rachitic, and it might be interesting to notice that under the benefits of better diet which they received at the hospital, better beds, better ventilation, and clothing, they invariably improved, and for the most part got entirely well. The limit of their stay on the island was five years, and it was noticed that whenever they were treated there for more than one year they improved with but little surgical interference.

Dr. M. Josiah Roberts remarked with reference to the first question, What cases can be safely left to nature, that the fact must not be overlooked that the death-rate in childhood far exceeded that of any other period of life. This was especially true of those children who were the subjects of constitutional disease, and therefore might explain the scarcity of these deformities seen in adults. Besides this, recovery from the deformity was one of degree, and we must distinguish definitely what was meant by a cure, when complete recovery was spoken of; and when speaking of complete cures, it was necessary to ascertain that the cure did not fall short of the positive normal standard. He would venture that he could show any gentleman who would walk with him through the best parts of the city numerous cases of knock-knees and bow-legs in slight degree, and yet it would be found that the patients were incapable of prolonged locomotion, or of standing upon their feet for long periods of time. It did not always require, in a case of knock-knee, or in-knee, a deformity of more than from two to five degrees to cause very considerable inconvenience.

While he agreed with the author of the paper that there were cases which recovered spontaneously, he wished to impress the fact that all the cases which were supposed to be cures were not complete recoveries. Dr. Roberts then exhibited a series of photographs illustrating the improvement which occurs from two years of age upward until fourteen years of age is reached, when the deformity was apparently completely removed; but the photographs showed that it still remained to a moderate degree.

With reference to the statement made by the author of the paper, that in most cases of bow-legs the deformity was due to the continuous curve from the hips to the malleoli, he wished to take exception. While the deformity appears to be largely in the shaft of the femur and of the tibia, these were in fact quite straight, and the deformity was confined mainly to the ends of the bones. Dr. Roberts exhibited photographs illustrating this point, and made the general statement that, in all cases of deformity we must expect the deforming influences to manifest themselves where there is the greatest mobility, namely, at the articulations. Next in frequency are the points which are separated by cartilaginous substance, as the diaphyses and epiphyses. In bow-legs the principal changes had taken place at the articulations between the epiphyses and the shafts of bones.

With reference to what cases can be left to nature, while he admitted that certain cases did recover, he was thoroughly convinced that in every case recovery might be aided by surgical appliances, and that the patient could get well in a much shorter time with surgical assistance than when left to nature.

With reference to manual force, he agreed with Dr. Poore, that it is applicable only in a limited number of cases, where the bones are very soft indeed. In nearly all such cases cure can be effected by means of mechanical appliances, and the limbs made absolutely straight, as determined by goneometric observations.

Dr. Roberts then spoke of the necessity of using instruments of precision in determining the degree of deformity which is present.

With reference to mechanical appliances, the theories once in use were good in their way, many of them were excellent; but he did not think that the ultimatum had yet been reached in the application of force for the correction of deformities. He then described at some length an apparatus for treatment by means of adhesive plaster, devised by the founder of orthopedy in this country, Dr. Davis, of New York. He also spoke to considerable length concerning osteoclasis and osteotomy, and closed with a description of his electro-osteotome, with which he had performed a large number of osteotomies.

Dr. Hopkins referred to a case in which he performed excision of the joint for knock-knee.

The President asked for information with regard to one point, namely, what was the experience concerning the influence of sex as affecting the frequency of the disease, and also as affecting the frequency of spontaneous cure. The reason he asked was because it had occurred frequently to him to have anxious mothers express great solicitude with regard to the presence of bow-legs or knock-knee in their children. He had been in the habit of saying to them, "Wait and let us see what the result will be," and in most instances perfect recoveries, so far as he had been able to ascertain, had taken place before adult life was reached.

Dr. Gibney, in closing the discussion, remarked with reference to the question asked by the President, that so far as he was able to recollect the cases of bow-leg and

knock-knee occurred about equally in the sexes. One of the results which he had noticed in these cases, however, had been what is known as flat-foot, and whenever at the Hospital for the Ruptured and Crippled he had seen a case of flat-foot he made further inquiry, and almost invariably found that the patient had during childhood suffered from bow-legs.

With reference to the death-rate among children, mentioned by Dr. Roberts as affecting the number of cases of deformity of the lower extremities seen in adults, he would remark that in Glasgow it was a notable fact that bow-legs and knock-knees among adults were very numerous, and therefore that the number was probably not affected materially by the death-rate occurring in children in that city. The cases of adults which he had seen had been mostly in stout persons, and belonged to the form which Dr. Little, of London, had termed atonic knock-knee, without the existence of bone deformity in early life.

With reference to the class of cases referred to by Dr. Hopkins, he could only say that his paper was restricted to the treatment of rachitic deformities.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DISCUSSION AT THE MEDICAL SOCIETY OF LONDON ON "LANCING CHILDREN'S GUMS"—MYXŒDEMA—EFFECT OF EXTIRPATION OF THE THYROID BODY.

LONDON, November 8, 1884.

Our societies are all now in full work. On Monday last at the oldest society, the entire evening was occupied with the subject of lancing the gums in children. This was introduced in a racy statement of his opinions by Mr. Edmund Owen, Surgeon to St. Mary's Hospital and to the Children's Hospital. His first reason for bringing it forward was, he said, his slight practical acquaintance with the subject, and though he told us that he had carried a gum-lancet in his card-case for years, he added that he found no work for it upon infantile gums. This experience precisely agrees with my own. In youth indeed I lanced many a baby's gums, it is to be hoped with benefit; but later on, as fashions changed, I thought out what ought to be the reasons for doing so, and resolved that I would look for the tumefaction and redness I had been taught would certainly appear if this necessary operation were delayed, or that I would wait until such evident obstruction to the eruption of teeth occurred as we sometimes see in the case of wisdom teeth in older patients. The result has been that though I have sometimes assisted the emergence of an adult's wisdom tooth, my baby-patients have escaped scot-free. But to return to the discussion, Mr. Owen said how often do we hear this remark, "My children always cut their teeth with diarrhœa or a large head," and the explanation of this he considered was to be found in improper feeding, an opinion which everyone who observes the folly of parents in this respect will be ready to endorse. They stuff their babies' stomachs with food which they cannot digest, and then declare that the diarrhœa and other disorders thus brought about are only due to teething. But surely teething is a natural process—not the efficient cause of the many disorders to which the susceptible infantile body is liable. No doubt when a gum is inflamed scarification would ease it, but when it is not this remedy is not indicated. One very significant suggestion was made by Mr. Owen, viz., to keep a sharp lookout for essential paralysis, which comes on so insidiously at a period when the symptoms are likely to be attributed to dentition. In the discussion which followed Dr. Clement Godson, Dr. Braxton Hicks, and Dr. C. J. Hare, as well as others, put in a plea for the "good remedy out of fashion," and Mr. H. Cartwright threw in his authority as a dentist in favor of the notion that diarrhœa and convulsions may be caused by dentition. The chief indication he assigned for the operation was a tense glistening state of the gum when the tooth was about to come forward, or greatly swollen or inflamed gums. Dr. W. A. Duncan had seen the operation relieve diarrhœa and convulsions; Dr. Ewart was a firm believer in the lancet; Dr. Drew thought it indicated in a febrile condition with pain in the gums lasting for two days, as well as in some cases of diarrhœa, bronchitis and otitis. Dr. S. Taylor would use it in a horny condition of the gums; and Dr. Webb had seen children on the point of death saved by it. On the other hand, Dr. Travers had not seen a single instance in which he felt justified in lancing the gums in the last nineteen years. Mr. Lowne said dentition was a physiological process and nine out of ten cases of diarrhœa were caused by improper feeding, and he could not understand how that complaint could be brought about reflexly by dentition. Dr. Sansom thought there was a liability to use the lancet too frequently. Dr. Hall thought it had fallen into disuse since the introduction of bromides, and some other speakers "damned with faint praise" the instrument with which most of them had probably in younger days tortured their little patients. In reporting so fully a discussion which some of your readers may perhaps think trivial, it may be right to add that this was one of the most interesting evenings of the session.

A case of myxœdema was brought forward at a recent meeting of the Clinical Society, which was interesting from a history of its commencement in a severe attack of hemorrhage and the continuance of a hemorrhagic tendency; besides which the patient suffered from occasional attacks of nervous restlessness, which are not only unusual but may almost be thought to be incompatible with myxœdema. A curious circumstance may also be added respecting treatment: the patient felt herself a good deal better while under half-drachm doses of tincture of jaborandi, and there was at the same time a great increase in the excretion of urea; but no other objective improvement.

In connection with the case above mentioned, attention was once more called to the effect of extirpation of the thyroid gland. It will be remembered that last year Dr. Kocher, of Berne, reported that he had observed after this operation, in a number of cases, the development of a cachexia closely resembling the condition of myxœdema; and a conjecture was ventured that this disease might represent in adult life the state of cretinism at an earlier period. Be that as it may, the number of Kocher's cases was sufficient to show that excision of the thyroid body is in some way related to the strumous cachexia he had described, although partial extirpation was followed by no such condition. The notion first put forward by Dr. Semon, that this state was connected with cretinism, received some confirmation from a case now reported by Professor Paul Bruns. His patient, now twenty-eight years old, had the thyroid removed eighteen years ago. In 1867, five months after the operation, his disposition had completely changed. From a bright, lively child he had become very retired and quiet, and he now is a dwarf and a cretin. After the operation the development of the trunk and limbs had ceased and only the head had grown to the size of manhood. The expression is that of an idiot, the skin and mucous membranes are pale. The whole integument is dry, brittle, and thickened by a peculiar soft gelatinous infiltration. There is also swelling of the tongue, palate, and tonsils, giving rise to slow, difficult speech. Sensibility and muscular power preserved, but the patient cannot work, can hardly walk fifty steps. His mental faculties are less developed than those of a boy of ten. This important case seems to furnish us with a blending of myxœdema and cretinism, and it was suggested that both conditions are due to the

loss of the thyroid gland. Certainly some of the other facts recorded point in the same direction, but they seem at present scarcely sufficient to establish so large a generalization, and in this case it would be easy to suggest another explanation.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 16 to November 22, 1884.

McKEE, JAMES C., Major and Surgeon. Leave of absence extended one month. S. O. 273, A. G. O., November 20, 1884.

GODDARD, C. E., Major and Surgeon. Assigned to duty at Fort Yates, D. T. S. O. 138, Department of Dakota, November 15, 1884.

COWDREY, S. G., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 237, Department of the East, November 17, 1884.

HAVARD, VALERY, Captain and Assistant Surgeon. Granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be dispensed with at his present station. S. O. 268, A. G. O., November 14, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Omaha, Neb., and ordered for duty at Fort D. A. Russell, Wyo. T. S. O. 101, Department of the Platte, November 19, 1884.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Keogh, M. T. S. O. 134, Department of Dakota, November 5, 1884.

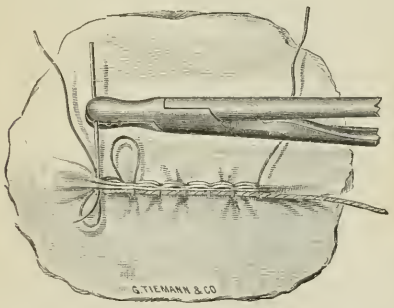
New Instruments.

A RAPID METHOD OF CONTINUOUS SUTURE.

By P. J. PRENDERGAST, M.D.,
BROOKLYN, N. Y.

AFTER having used the needle of Dr. Wackerhagen with great satisfaction for interrupted suture, I have found that it can also be used for the continuous suture, and that by a very rapid method, without utilizing the eye in the blunt end. The plan is as follows, viz.:

The thread having been passed under the bridge of the needle, each portion being of equal length, the



needle-holder is applied; the needle is then passed through the tissues and a loop of thread is drawn out, a piece of large size catgut is now passed through the loops by an assistant, each time the needle is withdrawn.

By this process we possess a double advantage—non-disturbance of the needle-holder, and one threading of needle for ordinary cases. I doubt not this needle will henceforth be used as frequently and satisfactorily for the continuous as for the interrupted suture.

A NEW ELECTRIC OTOSCOPE.

By ROSWELL PARK, M.D.,
BUFFALO, N. Y.

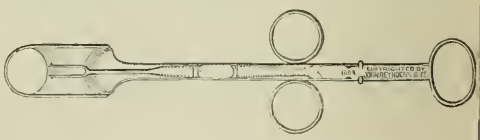
To those who have a means of supplying by some form of battery in their office an electric current of sufficient power, this little instrument will commend itself as a most convenient demonstrating otoscope, and one by which searching examinations can be made irrespective of time of day or light.

It consists of an otoscope of conventional pattern, much like Brunton's or Hasenstein's, from which the ordinary flaring, funnel-like side tube for collecting the rays of artificial light has been removed, and in its place a thimble inserted within which is the platinum coil made white hot by the passage of the current. The battery wires are connected with a perforated flange on either side the thimble, and a little knob to be pressed down by a finger of the hand which holds the instrument makes the connection in its interior, so that the light is under perfect control. Back of the coil is a dead white mirror

surface which serves to economize and intensify the light. The portion of the instrument corresponding to the ear-speculum proper is made in three sizes, and of polished metal, or of hard rubber, as may be desired. The thimble fits easily in its socket, and is turned half round as the instrument is changed from one ear to the other, so that the knob may, if desired, always have the same relative position. And when sunlight or artificial light from a lamp are wanted the thimble is entirely removed and the funnel-tube inserted. The battery used may be one of the little storage batteries accompanying Trouvé's "polyscope," a cautery battery, or any other supplying sufficient intensity.

MARCONI'S TONSILLITOME.

IN this instrument the Mackenzie blade is combined with Matthews' fork and handle, each of which are the



superior features in the respective instruments. The advantages of this instrument will readily appear to those within whose specialty of practice it falls.

A DENTIST at Triangle, N. Y., once received an order for a block of teeth, as follows: "My mouth is 3 inches acrost, $\frac{5}{8}$ inches through the jaw; sum humocky on the edge; shaped like a horse-shoe, toe forward. If you want me to be more particklar I shel hav to cum thar. Yours truly, ——."

Original Articles.

CONCUSSION OF THE SPINE AND ITS RELATION TO NEURASTHENIA AND HYSTERIA.[1]

By C. L. DANA, A.M., M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE physician who is called into court to testify in a case of spinal injury witnesses a curious spectacle. The lawyer for the prosecution waves before the jury a volume of "Erichsen upon Spinal Concussion." He reads to them, in impressive accents, the statement that every injury to the spine, however slight, is full of danger to the sufferer. He asks, with sonorous emphasis, if Mr. Erichsen is not a surgeon of world-wide fame; and if he does not say that slight injuries to the back may cause chronic spinal disease of the most serious character. He sneers at the work of a certain Mr. Page, who is known to be professedly only a railway surgeon. He shows that his client has paralysis, anæmia, meningitis, in fine, "spinal concussion."

On the other hand, the lawyer for the defence brandishes triumphantly a larger work, by Mr. Herbert Page, on "Injuries to the Spine;" he reads to the jury cases of malingering therein related, shows that Mr. Erichsen has for years made a business of being an expert for people with injured spines, but that he has never yet found a case that proved fatal. He quotes Mr. Page's two hundred and thirty four cases of spinal concussion, in most of which recovery resulted, and shows, through his medical expert, that the spinal cord is so admirably protected that it could never possibly be injured by anything so utterly trivial as a railway collision.

The medical experts themselves in these cases necessarily testify in the most diverse way, according to their natural bias or the particular surgical authority or pecuniary support upon which they rely. And authorities are so unsettled and contradictory, and symptomatological data so uncertain, that two medical men can with perfect honesty, if they go by written works, support quite opposite views.

It is on account of the existence of this uncertain state of written medical opinion that I venture to present the subject of spinal concussion now. I do not so much wish to offer any original views of my own, or detail my personal experience (which has been sufficient to show me in how unsatisfactory a state the subject of spinal concussion is), but rather to lay down the mooted questions regarding injuries to the spine and their sequelæ, to present what is in my opinion the just and proper view to take of them, and to ask for corroboration or criticism of my audience to-night.

Under the term concussion of the spine Mr. Erichsen includes four different conditions:

First.—Concussion of the spinal cord itself. Here a jar or shake of the cord disorders or suspends its functions without causing any detectable lesion.

Second.—Spinal hemorrhage and compression.

Third.—Acute and subacute inflammation of meninges and cord.

Fourth.—Chronic meningitis and myelitis, consequent upon simple concussions of the cord, apoplexies, or acute or subacute inflammations.

He describes as accompanying or following these injuries symptoms attributed to general nervous shock. These symptoms are those of cerebral irritability and asthenia, spinal anæmia and irritation, and a long series of visual troubles. Without going into any analysis I think I can say from a careful reading of his book that Mr. Erichsen's teachings and their implications are somewhat as follows:

That there is such a thing as concussion of the spinal cord, pure and simple, whereby the functions of the cord are temporarily suspended.

That such a concussion of the cord may be followed by recovery (and generally is), or by death or chronic disease.

That there is such a thing as concussion of the spine, wherein the whole vertebral column, with its envelopes and contents, is jarred or injured in various ways.

That this term, "concussion of the spine," is one of the widest inclusiveness, taking in symptoms of injury to the cord, of injury to the vertebral column and muscles, and of general nervous shock and its sequelæ.

That an injury to the spine or body may prove most serious (to the spine especially), and that even trivial injuries may cause grave organic disease of the cord or its membranes.

That spinal anæmia, spinal irritation, hysteria, and allied troubles may result from slight injuries to the spine, and the nervous shock of the accidents causing them.

That these last-mentioned symptoms, as well as those of a supposed chronic meningo-myelitis, may develop later, and slowly, after a period of comparative health, and that they are very serious in character.

That malingering occurs and should be looked out for.

That serious visual troubles occur.

I might add here that Mr. Erichsen reports in support of these views thirty-one cases in detail, of which nine were the result of railway accidents.

Turning now to Mr. Page's work, already referred to, it should be said in the beginning that it is by no means an aggressive criticism of Erichsen alone. The writer endeavors to produce a systematic treatise, and although he puts his arguments together badly, he has succeeded in making an original and valuable contribution to the subject in hand. It is true, however, that much space is devoted to pulling down some of the pathological creations of the London Hospital surgeon's fancy. Without attempting at all to analyze his book, I propose to set off the synopsis given of Mr. Erichsen's teachings by certain propositions, which I believe to embody the opinions of Mr. Page, and then to enumerate the mooted points between them. The views of Mr. Page, so far as I understand him, are:

That the existence of such a thing as concussion of the spinal cord, pure and simple, is unproven and extremely doubtful.

That the spinal cord cannot be directly contused or injured by shakes, blows, or violence to the body unless there is a fracture or dislocation of the spinal column.

[1] Read at a meeting of the New York Neurological Society, November 11, 1884. According to Poor (Railroad Manual, 1884), there are 289,190,783 passengers carried upon the 113,329 miles of road in the United States yearly in 1882). This is about six times the total population. For the Middle States the number of passengers is ten per cent. of the population, and for New York about fifty million. Among these fifty million there occurred in 1882–83, according to the Report of the New York Railway Commissioners, 40 deaths and 194 injuries. In addition to this there occurred to employés 175 deaths and 722 injuries, and to all others 280 deaths and 250 injuries, making the total casualty returns in this State for one year 495 deaths and 1,166 injuries. Calculating upon this basis, the number of deaths annually among railway passengers would be about 232, the number of injuries 1,125. For the whole country the total number of deaths would be not far from 2,871 among passengers, employés, and others, while the total number of injuries would be about 6,762.

That so-called cases of concussion of the cord, followed by softening and death, or by symptoms of myelitis, are cases of spinal apoplexy, or of dislocation or fracture with compression.

That the term concussion of the spine is arbitrary, vague, and misleading.

That injuries to the spine very rarely, if ever, produce chronic non-fatal forms of meningitis, myelitis, or meningo-myelitis, so called; but that the symptoms attributed to these conditions are the result of lumbago, strains, and ruptures of muscle and ligaments, injury to peripheral nerves, and general nervous shock, setting up neurasthenic and neuromimetic disorders.

That these neurasthenic and neuro-mimetic disorders, though often serious, are not fatal, but tend toward recovery; and that the patient and the litigation are often responsible for many of them.

That the symptoms being mostly subjective, it is difficult to exclude deception; that some unconscious deception often occurs, even with honest patients.

That no serious visual troubles follow in these chronic functional disorders.

The general tenor of Mr. Page's work is to the effect that the spinal cord is a very carefully protected and not easily injured organ. From a comparison of these views with those of Mr. Erichsen, we may learn what are the disputed points regarding the effects of injuries to the spine.

Put in the form of queries, they are as follows:

First.—Whether external violence can cause a simple concussion, and perhaps contusion of the cord, of a character analogous to concussion of the brain, or whether the cases heretofore so considered are really examples of spinal hemorrhage, or of dislocation, separation, or fracture with compression?

Second.—Whether external violence or jars can cause direct contusion of the cord, or produce a structural change that ends in softening, there being no lesion of the enveloping osseo-ligamentous parts?

Third.—Whether blows or jars, ever or often, set up a chronic meningo-myelitis or myelitis, no lesion of the spinal column being present?

It is to this last category that Mr. Erichsen relegates a large portion of his reported non-fatal cases of concussion of the spine, and we may put in here, therefore, the counter-query:

Whether in a very large number of cases of chronic nervous disturbance, following railway and other accidents, cases usually diagnosticated in a routine way as "concussion of the spine," or chronic meningo-myelitis, the disease is not really mental (neurasthenia, hysteria, hypochondriasis), or else partly mental and partly the result of injuries to the spinal muscles, ligaments, and nerves?

Fourth.—Finally, the question is raised, Whether serious organic visual troubles result from railway and other accidents in which the spine or body is injured, but not the eye directly?

Some of the foregoing queries have plainly a more scientific than practical interest. As to the first one, for example, that of the existence of a concussion of the spinal cord, pure and simple. We know that after violent blows or falls persons suffer from a temporary paraplegia. Whether this is due to a molecular disturbance of the tissue of the cord or to a spinal hemorrhage, the clinical facts are the same. But I believe that there is enough evidence to justify one in retaining the term "concussion of the cord," a term sanctioned by ancient authority and adopted by every surgical writer.

The evidence *pro* and *con*, collected by Erichsen, Page, and myself, is the following: Erb cites a case which he believes illustrates spinal concussion ("Ziemssen's Cyclopædia of Medicine," Art., Concussion of Spine), and guardedly admits its existence.[1]

[1] See bibliography.

Le Gros Clark also (op. cit.) thinks that the term concussion of the spinal cord, used analogously to concussion of the brain, is justifiable. He relates two cases apparently illustrating this, but admits later that there might be some organic lesion.

Shaw (op. cit.) cites a case where there was apparently simple concussion, but the patient died and the autopsy showed a hemorrhage in cord.

Dr. Abercrombie (op. cit.) relates the history of a case where a man was struck in the back with a rock and rendered paraplegic for several weeks; he ultimately recovered. Abercrombie's opinion, that there is a true simple concussion of the cord, is apparently based on this case, and on those of Boyer and Frank, to which authorities he refers.

Dr. T. Buzzard (*The Lancet*, 867, vol. i., pp. 389, 435, 509, 623) quotes a number of cases believed to illustrate concussion of the cord, taken from Dr. J. L. Casper's "Ueber des Verletzungen des Ruckenmarkes," 1823, Berlin. This author gives Frank's cases reported in his "Kleine Schriften," also one by Valsalva and other old authors.

Boyer (op. cit., p. 135) relates two cases. In one the patient was struck on the back, in the other he strained his back in a violent muscular exercise. Both became suddenly paraplegic, died in a few weeks, and upon autopsy no lesion of the cord was discoverable.

These cases are not conclusive, because no microscopical examination was made. In the second case there could not have possibly been any *concussion*, as the man was simply going through a difficult muscular exercise for the amusement of his friends.

Mayo (op. cit.) expresses the opinion that concussion of the spinal cord may cause complete suspension of its functions. His illustrative cases *may* be explained on the theory of a hemorrhage.

Syme ("Principles of Surgery," Third Edition, p. 433) states that the cord may have its functions suspended by a concussion, as does the brain. He states, however, that an effusion of blood or serum probably complicates these cases.

Dr. John A. Lidell (*American Journal of the Medical Sciences*, vol. xlviii., p. 305) expresses his belief in simple spinal cord concussion, and relates three cases illustrating it, as he believes. The paraplegia in these cases could be explained, however, by the injury to peripheral nerves or by hemorrhage.

Dr. S. Wilks ("Diseases of the Nervous System," p. 201) states that he has more than once seen a man receive a severe injury to the back, become paralyzed, and recover in a few days. Here he thinks the cord is stunned. He reports the case of a porter who received a severe blow on the head (?) and back. He was stunned for a time, but resumed work for three days, then developed paraplegia and died. Autopsy showed only a very slight granular and fatty change in the cord.

G. Fisher (*Deut. Zeitsch. Chir.*) cites the case of a man, aged twenty-one, who fell, striking on his back. There was complete paralysis of the extremities, trunk, and spinal centres. Death occurred. Post-mortem showed only a slight meningeal effusion. Paralysis was referred to shock.

I have taken the trouble to bring these cases together, adding a number not quoted by Erichsen or Page, because in the works of those authors the clinical and pathological evidence is not systematically arranged, and it is by no means easy in reading Mr. Page's book to follow his arguments and his evidence.

I. These cases may not of themselves positively prove the existence of a concussion of the cord. In view of the facts presented under the second query, however, showing that shakes and injuries can cause a softening of the cord, the certainty that it, in rare cases, can be "concussed," so as to suspend its functions, becomes very great.

II. As to whether jars and injuries to the spine can

cause direct structural change leading to softening of the cord, there being no lesion of the spinal column—

Sir Benjamin Brodie (op. cit.) first laid down the view that such a thing was possible. And though it is true that he cites no illustrative cases, yet he writes with a particularity which leads one to believe that he has seen such cases. As slightly confirmatory of this view also, Gull ("Guy's Hospital Reports," Series iii., 191, 1858, Case xxiii.) reports the case of a porter, who received a severe blow directly upon the cervical spine. There was paralysis of motion in the left arm, and of motion and sensation in legs. Post-mortem showed softening, with a slight ecchymosis in gray matter, and contusion of cord opposite fourth and fifth cervical vertebræ. The spine was normal, except for a separation of the bodies of the fourth and fifth cervical vertebræ.

The Lancet (April 19, 1877, p. 571) contains the report of the case of a Mr. John Jepson, who was bruised and shaken in a collision. He attended to his business for a fortnight. Symptoms of spinal concussion then set in: spinal tenderness, muscular twitchings, paraplegia, mental symptoms. In six months he died of pneumonia. Post-mortem showed considerable softening in the dorsal portion of the cord.

Mr. Curling ("Transactions of Pathological Society," vol. viii.) records the case of a boy, aged eight, who fell, striking on the buttocks, became paraplegic, and died in three months and a half. Post-mortem showed cord softened in several places.

Dr. Lochner, of Schwalbach (*Aertzliches Intelligenzblatt*, October 19, 1875), reports two cases of softening of the cord following a blow or fall, no lesion of the spinal column being found. Dr. Abercrombie also cites a similar case (op. cit., p. 343).

III. As to whether injuries to the spine, shakes, and jars can cause a subacute or chronic myelitis or meningomyelitis, the spinal column not being injured. Undoubtedly some such cases do exist. In judging of this question, however, it is well to bear in mind that chronic myelitis and meningitis are serious, and eventually fatal, diseases. Therefore, if railway and other accidents produced them, pathologists would see them.

Mr. Page collects the histories of only two. One was reported by Mr. Hutchinson (*Medical Times and Gazette*, 1879, vol. i., p. 348). It was a case of paraplegia from myelitis following injury to the back. The patient recovered. The girl had a typical acute myelitis of the lower part of the cord. She had had inherited syphilis.

A second case was that of concussion-lesion, with myelitis and secondary degeneration, reported by Dr. Bastian ("Transactions of the Royal Medical and Chirurgical Society," June 25, 1867, vol. l.). Here the patient died, and a rupture of the cord in the cervical enlargement was found to have been the starting-point of the disease. Mr. Page considers this case unique.

I have under treatment now a patient suffering from transverse myelitis and descending degeneration, of whom the history is very similar to that of Bastian's. Before reading Mr. Page's comments, I came across Bastian's case, and was so struck with its clinical resemblance to my own that I referred to it in exhibiting the patient to my class at the New York Post-Graduate School.

Dr. Edes reports (quoted in Hamilton's "Medical Jurisprudence," p. 357) four cases of postero-lateral sclerosis, the result of spinal concussion.

Petit, in his work upon the "Relation of Locomotor Ataxia and Traumatism," shows that the injuries and accidents may at least develop tabes in the predisposed.

Althaus in his recent work on "Scleroses of the Cord" states the same.

It seems to me to be proven beyond a doubt, despite Mr. Page's arguments, that external violence and jars, apart from any hemorrhage or other lesion, may cause an acute, subacute, or a chronic myelitis, with softening or secondary degenerations. Not many of these cases have yet been reported, because they are rare and because there is not yet a widely diffused knowledge of the methods by which the different forms of chronic myelitis are diagnosticated. And it ought perhaps to be added that a certain predisposition, syphilitic or neurotic, is necessary for the development by traumatism of most of these forms.

But it is claimed not only that myelitis, but that a chronic meningitis or meningo-myelitis may be set up by concussions of the cord. It is to this pathological class that Mr. Erichsen relegates a very large part of his reported cases. In doing this he had undoubtedly given a more serious aspect to many of these cases than they deserved. Meningitis and myelitis are, as we have stated, serious diseases, yet the cases Mr. Erichsen describes do not die.

I fully agree with Mr. Page that a large proportion of these cases, when analyzed, can be shown to be cases of strain or rupture of muscular and ligamentous structures, injury to nerves, or the results of a general nervous shock, and that the spinal cord has no more to do with the disease than the stomach.

I hesitate to say, however, that Mr. Erichsen is entirely wrong in his pathology, or that there is not set up in some of these cases a low grade of meningeal inflammation or congestion; or even if there be not, as in the case of Mr. Jepson, patches of softening.

This is certain, however, that heretofore too little stress has been laid upon the symptoms produced by neuritis, strains, and general nervous shock.

Regarding these points some illustrative cases other than those quoted by Erichsen and Page may be found, Leyden (*Archiv f. Psychiatr.*, 1878, viii., p. 31, quoted by Hamilton) reports a case in which a patient suffered from peripachymeningitis and compressive myelitis ending in death.

I have reported a case of cervical pachymeningitis in a syphilitic where the disease was undoubtedly started up by a severe blow on the neck (*Journal of Nervous and Mental Diseases*, January, 1882).

Dr. Allan McLane Hamilton reports a case ("Medical Jurisprudence," p. 355, New York, 1883) in which he states that there was undoubtedly "serious organic change in the brain and cord" as the result of spinal concussion.

IV. As to the visual troubles, I doubt very much if the chronic functional disturbances we have been speaking of can ever produce any real organic trouble with vision.

Albutt, I believe, speaks of a chronic meningeal irritation, which gradually creeps up from the cord to the brain, and finally affects, by contiguity, the eye. I believe, however, that there may be asthenopia, restricted vision, hysterical disturbances of same, vascular changes in the disc, but nothing else, unless organic disease of the cord or brain sets in. Dr. J. G. Johnson gives a valuable summary of evidence on this point. *Vide* bibliography.

Turning now to a discussion of the more practical and important features in so-called spinal concussion, I would state that without doubt in the largest class of troubles resulting from accident and injury to the spine, the main source of the symptoms is a general functional nervous disturbance.

The fright, excitement, and more or less severe bodily injury produce often a profound shock. From this the nervous system gradually emerges into a state that may be broadly characterized as one of asthenia, morbid irritability, and defective inhibition. The patient then furnishes a clinical picture familiar to all.

Sleeplessness, irritability, states of depression, defective memory, inability to do mental or physical work, headache, tinnitus, nervousness, vaso-motor disturbances, excessive sweating, asthenopia, large pupils, spinal pain and tenderness, muscular weakness, tremor and twitchings, and irregular pulse, are the ordinary symptoms. Sometimes pronounced neuromimetic disorders develop. The patient shows the symptoms of so-called spinal anæmia, or of spinal irritation, or he develops paralyses

hemianæsthesia, and various hysterical phenomena. In nearly all cases these symptoms are subjective. They correspond with those of neurasthenia, as described by Beard, Mitchell, Erb, Möbius, and Dowse, or with those of the convalescent stage of cerebral concussion, as described by Hutchinson; they are included under the neuromimetic disorders of Paget, and they have been aptly termed railway hysteria and hypochondriasis by Dr. Allan McLane Hamilton.

It is these cases which form the most puzzling problems for the physician, and which cause him the greatest trouble, perhaps bring him into greatest reproach before the court.

This is due partly to the incompletely developed views, to speak mildly, promulgated of late years regarding the nature of spinal injuries, and partly to the natural and inherent difficulties of the subject. As to the first point, the spinal column has been held up as the most delicate, responsive, and hyperæsthetic of all organs. It has been made the focus for every jar, bruise, or shock to centre upon, and "concussion of the spine" has been the shibboleth of every frightened passenger and prosecuting attorney for twenty years. As Holmes once said regarding Bishop Berkeley and his belief in the universal efficacy of tar-water: "Berkeley believed that the whole material universe was nothing, and that tar-water was everything," so in a measure the spinal cord has been looked upon as everything—brain, muscle, ligament, and nerve as nothing.

Not long ago, through the kindness of my friend Dr. George E. Munroe, I was called to see three women who all had very nearly similar symptoms, viz.: mentally they were profoundly emotional and hysterical, physically they were paraplegic, or nearly so, and suffered from sensitive spines. In two the spinal pain and tenderness were so very marked that the diagnosis of spinal irritation was made; the third patient had what was termed spinal anæmia. This last patient only was in a railway collision, and received a slight jar, but no serious physical injury. The other two received severe blows on the head, causing concussion of the brain. Thus the fright of a collision in one case produced a similar state to that caused by the blows on the head in the other two. But only the patient who was in the railway accident was thought to have "concussion of the spine."

It may be laid down as absolutely established now, that railway accidents produce severe shocks to the nervous system which make persons neurasthenic or hysterical, oftener the former. This condition is a real pathological one, and the sufferers are unquestionably sometimes as much injured as if they had had a broken arm or leg, or an actual injury of the cord. The practical trouble is in determining how ill such people are, how much they are malingering, how much the prospect of heavy damages unconsciously or consciously affects their symptoms, how much predisposed to disease they were before the accident. For a road should not be called to account because it does not provide perfectly for the crippled, the paralytic, and the valetudinarian.

In illustration of these difficulties my learned friend Dr. Allan McLane Hamilton records, in his valuable work on "Medical Jurisprudence," the history of a patient of mine (whom he examined for a railroad company), and adds this terminal comment: "This man is an undoubted malingerer." In opposition to this view, I have for the three years since his accident thought him to have been made by it a nuisance to his family and a burden to himself on account of his change of disposition, lessened capacity to work, and sciatic pains. If ever I attain a position which will justify me in writing a medico-legal treatise, I shall record the same case and say that this man was undoubtedly a case of traumatic neurasthenia complicated with neuritis. But who is ever to decide whether my book will be right, or Dr. Hamilton's?

It will be seen that it is an important matter to understand and extend the means of diagnosing these conditions where nearly every symptom is subjective. Into the discussion of this I cannot enter, but would call attention to the occasional evidence of hemianæsthesia of the body and of the special senses as a sign of hysteria. Drs. G. L. Walton and J. J. Putnam have especially drawn attention to these signs, and to the occasional very great value of the tuning-fork, æsthesiometer, and visual tests.

The use of electricity in testing muscular and nerve irritability and degeneration when carefully applied is of the greatest value. At the last meeting of the American Neurological Association, I suggested that the test of diminished or increased electrical resistance in affected limbs might be of value in some cases. In one case in which I tried it, the alleged lame and injured limb showed slight diminished electrical irritability, and increased electrical resistance on two successive trials on different days.

The matter of prognosis, also, calls for more accurate determination. Mr. Page is inclined to take a rose-colored view of the prognosis in these cases. He thinks that a large majority recover, and that nearly all tend to recovery. He does not seem to have met cases like those of Buzzard,[1] or where any organic disease finally set in, as in Edes' cases, Petit's, and my own. He never has met any serious results to vision, as have Wharton, Jones, and Erichsen.

His views are rather too hopeful, and decidedly are not always borne out by his own notes. "Patient improving at last accounts," is a formula given, but it may mean very little after all. Traumatic neurasthenia, or railway hysteria, is generally recovered from in a great measure. In my experience traumatic neurasthenia is the most amenable form to treatment. But it is very often the case that the man who has had a severe nervous shock is never entirely the same that he was before. This is particularly the case if he has reached middle life, or is of a neuropathic constitution. The very old and the very young seem to suffer less.[2]

The object of my paper has been to show:

1. That the term spinal concussion is a misleading, and often incorrect one, and that the symptoms which are usually associated with that name are really symptoms of traumatic neurasthenia,[3] hysteria, and hypochondriasis, associated, more or less, with symptoms of injury to the vertebral ligaments and muscles, and to the spinal nerves; that, in other words, spinal concussion is mental shock and physical bruising.

2. That this traumatic neurasthenia is in a measure a real disease, though it is very hard to say how much is real and how much the patient puts on.

3. That it may be, and often is, simulated, and that it requires the greatest care to detect skilled impostors.

4. That we need more objective tests for the purpose of determining the existence of these subjective neuroses.

5. That the prognosis of railway or traumatic neurasthenia and hysteria is very good so far as steady improvement is concerned, not so good as regards complete recovery.

6. That concussion of the spinal *cord* alone, followed by temporary loss of function, or by myelitis, does occur in rare instances.

7. That, in the predisposed at least, injuries and jars may set up chronic myelitis, without there being a lesion of the spinal column.

8. That Mr. Erichsen has in his book on "Spinal

[1] Nearly twenty years ago, Dr. T. Buzzard (Lancet, 1865 and 1867, loc. cit.) investigated the after-histories of eight cases of cerebral and spinal concussion. Two to four years later, none were found well, and one had died of phthisis. The same author cites cases apparently showing that spinal concussion may develop pneumonia, phthisis, imbecility, convulsions, diabetes, aneurism. In his cases, however, there seems to have been an element of brain injury.

Moeli (Archiv f. Psych) relates the history of four cases of railway injury followed by mental disturbances.

[2] It would be interesting to learn of the cures which railway and other accidents sometimes bring about. See H. Tuke's work on Body and Mind.

[3] The term "traumatic neurasthenia" covers a well-recognized symptom-complex which, in some cases, includes a lithæmic condition produced by active, healthy persons being suddenly obliged to lead a sedentary life.

Concussion" erroneously attributed functional troubles to the results of organic spinal disease.

9. That Mr. Erichsen's book on "Spinal Concussion" has a strong tendency erroneously to attribute to a shaking of the spine and a supposed ensuing meningitis, symptoms really due to mental shock, peripheral injury, or malingering.

Nature of injury.	Pathological change produced.	Symptoms.	Result.
Severe blow, fall, or shake.	Fracture or dislocation of vertebræ; compression or crush of cord; perhaps a hemorrhage in spinal cord or canal.	Immediate paralysis or paresis of limbs and spinal centres; anæsthesia; reflexes abolished.	Death occurring soon. Slow improvement, with symptoms of severe organic disease.
Severe blow, fall, or shake.	True concussion of spine (very rare); spinal contusion (very rare); spinal hemorrhage (not uncommon). With above are some injuries to ligaments and muscle, perhaps concealed fracture or dislocation; injury of nerves.	Temporary paresis or paralysis lasting one to six weeks; gradual recovery, spinal pains, symptoms of nervous shock.	Steady improvement and gradual recovery (the rule). With or without a preliminary period of comparative health or temporary improvement, symptoms of traumatic neurasthenia, hysteria (less often), or hypochondriasis, litigation symptoms appear (improvement and cure the rule). In very rare cases meningo-myelitis, insanity, epilepsy, inebriety, diabetes result.
Slight blow, fall, or shake.	More or less bruising, strain, or rupture of muscle and ligaments; some injury of nerves.	Sometimes a temporary paralysis (psychical); symptoms of general nervous shock or of concussion of brain; pains, stiffness, impaired gait.	After a period of comparative health symptoms of chronic meningitis or of chronic myelitis (tabes, lateral sclerosis) develop (very rare and only in the predisposed), traumatic hysteria, or neurasthenia. Gradual improvement the rule, and perfect cure the exception.

NITRITE OF AMYL AND ABORTION.—Dr. Samuel W. Francis reports that, having occasion to use a three-drop pearl of nitrite of amyl to restore a feeble patient, a young woman in attendance—and who, unknown to him, had been pregnant some six months—was so seriously affected by the vapor that she had to leave the room; and for several hours it was feared that she would abort. The doctor adds: "Might it not be well, under these circumstances, to study the action of nitrite of amyl as to its influence on the parturient female?"

LEAD-POISONING.[1]

BY R. CHANNING M. PAGE, M.D.,

NEW YORK.

PAROXYSMS of abdominal pain and obstinate constipation are the prominent symptoms of what is commonly called lead colic.

It is unnecessary to mention the many other well-known names that have been applied to this condition. Sometimes, however, it is called Madrid colic, but according to Larry that complaint is due to atmospheric vicissitudes and acid beverages, and not to lead-poisoning. The same may be said of the so-called West India colic, if we are to believe Drs. Chisholm and Thomson, who resided long in the West Indies. The symptoms of lead colic had been described from early times, but the real cause was unknown up to the time of Stockhausen, of Prussia, who first suggested it in a treatise published in 1656. Afterward Henkel first proved by actual experiment that lead and its compounds are the sole substances which produce lead colic.[2]

The etiology of the disease, as is well known, is the introduction into the system of lead in some form, either through the skin, the air-passages, or the stomach. The various ways in which people become poisoned with lead are well known, and need not be stated here. Suffice it to say that painters who work inside (dryers) are affected far more frequently than others. This is partly because they are compelled to work with doors and windows closed at all seasons of the year, and partly, I think, because the paint they use is mixed with turpentine, which is a highly volatile substance. Outside painters, on the contrary, not only have abundant ventilation, but the paint they use is mixed with a fixed oil.

A person once attacked is more liable to a recurrence of the disease, however thoroughly he may have been cured before resuming his occupation.

Men are much more frequently attacked than women, for the obvious reason that they are much more frequently exposed to the cause. The season of the year does not appear to have any influence in producing the disease. During the month of February, 1881, I had more cases to apply to me for treatment than at any previous time, and I began to think that perhaps in cold weather it might occur more frequently, but I have since noticed that fully as many are affected in warm weather. Inside painters have told me that they suffer more in summer than winter, as they work with doors and windows closed at all seasons. Vegetation suffers near lead furnaces, and cattle and hogs in the neighborhood die from lead-poisoning.[3]

The symptoms of lead colic are so well known that I need not repeat them all here, and the diagnosis is not difficult. Abdominal pain and obstinate constipation, as already stated, are the prominent features of an attack. The pain is sometimes intermittent; at others it is never entirely absent, but exacerbates and remits, so to speak. The obstinate constipation is owing to an entirely different cause from that which produces the general costiveness incident to lead-poisoning. The former is due to the pain, as we shall presently endeavor to describe, and sometimes fails to be overcome by drastic cathartics; the latter is associated with the condition of general bad health that has been brought about, and often yields to the ordinary laxatives.

Unless the patient is completely cured, and especially if he continues to be exposed to the influence of the poison, chronic symptoms appear sooner or later. Besides a condition of general bad health there is now paralysis of the extensor muscles of the forearm, causing what is commonly called drop-wrist. In some cases, as among miners, inside painters, and others who are ex-

osed to the vapors of lead, tremors are developed resembling paralysis agitans. In other cases arthralgia occurs, so that the patient imagines that he has rheumatism of the joints. These cases appear to be comparatively rare, however, since of twenty-six cases that applied to me for treatment at the Northwestern Dispensary, in this city, only two had tremor, and that of the upper extremities, and one had arthralgia. In all three cases the lead cachexia was well marked. I have had as yet but little experience with lead encephalopathy. The so-called *blue line* along the gums was first mentioned by Dr. Henry Burton, of London, in 1840.[1] Since then this sign has been insisted upon by nearly all authors on the subject as diagnostic. It is said to be due to the chemical action on lead of sulphuretted hydrogen generated about unclean teeth. For although the sulphide (sulphuret) of lead is black, under certain conditions it may, so far as I know, appear blue. Niemeyer, however, does not mention any blue line at all, but says [2] that "the gums are dark, almost slate-gray, the teeth themselves being discolored," a condition that may evidently exist without lead-poisoning. Flint [3] says truthfully that the blue line is not constant, and does not occur where the teeth are missing. Taylor [4] says that mercury and the salts of silver produce this blue line, and that in certain cases of chronic lead-poisoning it may be absent. All the blue line I ever found existed as frequently without lead-poisoning as with it. Bad and unclean teeth, I am inclined to think, will produce this so-called blue line along the gums independently of lead-poisoning. Even if it can be due to this cause, it would probably be absent in cases so slightly affected as to give rise to any doubt in the diagnosis. Beyond being an occasional clinical curiosity, therefore, even if it be that, it appears to be of little or no importance.

The duration of an attack of lead colic varies in different cases and the way in which it is treated. Thus under proper treatment it may last only a few hours or days at most, whereas if let alone, or in those cases where the patient seeks the advice of a druggist and undertakes his own treatment, an attack may last in varying degree of intensity for a week, or even indefinitely. The symptoms of chronic lead-poisoning, on the contrary, even under the best treatment, may continue for weeks and sometimes months. I once treated a patient with drop-wrist steadily for five months before he was cured. In other cases, undoubtedly, the duration is much longer, especially if the patient continues to be exposed to the poison.

The prognosis is nearly always favorable except in those chronic cases where general tremor has resulted, or where some grave complication has arisen. Thus it is said that a patient may die of apoplexy, or in an epileptic convulsion, during an attack of lead colic, or from supervening inflammation in some of the abdominal viscera, although I have never seen any of these cases. As the disease becomes chronic, defective nutrition, general emaciation, and chronic nephritis with a fatal result may occur.

The pathology of lead-poisoning may be said to be yet a subject for dispute. It is quite probable, however, that the motor cells of the anterior horns of the gray substance of the spinal cord are primarily affected.[5] We know that strychnine exalts the functions of these cells, and it appears that lead, on the contrary, in poisonous doses, depresses them. The muscles become affected accordingly. Thus in certain cases there is paralysis of the extensor muscles of the forearm, causing the characteristic drop-wrist. They naturally yield first, being weaker than the flexors. Subsequently, however, the paralysis may extend to other muscles of the body, including flexors also. Hence in some chronic cases we not only find drop-wrist, but also atrophy of the flexor muscles of the thenar eminences. There is reason to believe that all the voluntary muscles may become more or less affected as the disease progresses, only it is more noticeable in the extensors. However this may be, I believe with Romberg that the paroxysms of abdominal pain are neuralgic in character. Constipation cannot account for it, since a patient may be as regular in his bowels up to the time of an attack of lead colic as could be expected in one who was already in a state of general bad health, and whose intestinal mucous membrane was under the astringent influence of lead, if it had any. The attack once commenced, however, the bowels become markedly constipated, and as the pain increases in severity the more obstinate is the constipation. The reason of this is obvious. For as in pleurodynia, sciatica, and similar painful affections muscular movements become limited, so does intestinal neuralgia lessen peristaltic action. If the pain be very severe, as in some cases, peristaltic action is lost altogether, so that the bowels become absolutely motionless. Hence the obstinate constipation. To give drastic cathartics in such cases, therefore, without some anodyne, either in combination or previously administered, under the idea that moving the bowels will cure the pain, only aggravates the latter, and is unscientific practice. Just the reverse of this is the truth. Allay the pain and the bowels will often move without a cathartic. I usually give the two combined, however, as will presently be described.

It is clear that this temporary condition of obstinate constipation is not due to lead paralysis and atrophy of the muscular coat of the intestines, otherwise it would be more permanent. On the contrary there are cases with complete drop-wrist whose bowels are perfectly regular.

Neither can pain be due to inflammation of the intestinal mucous membrane, or to spasm of the muscular coat of the bowels, otherwise, instead of obstinate constipation there should be diarrhœa or dysentery. Moreover, in those cases where post-mortem examination has been made, no trace of inflammation was usually found, and it is hardly possible for muscular spasm to continue without interruption for a week, as lead colic sometimes does. Collections of gas in the intestines cannot account for the pain, since they are not always noticeably present, nor is relief usually accompanied by marked escape of flatus, as in wind colic.

In regard to treatment, prophylaxis by avoiding exposure to the cause as far as practicable is of the first importance. Milk, as recommended by some, is a prophylactic so far as it is an article of nourishment. For that reason it is better than dilute sulphuric acid, which is of no value and is fit only for washing the hands. It was first introduced by Gendrin, in imitation somewhat of the alum treatment originated by Grashuis, on the theory that it would produce in the system the insoluble sulphate of lead, which was supposed to be inert. Clinical observation, however, disproves this theory. The judicious use of iodide of potassium, producing in the system the soluble iodide of lead, which is readily eliminated, would, I think, be a much better plan. Should lead colic occur, however, the immediate indications are, obviously, to allay pain and, on general principles, to evacuate the bowels. Perhaps the best and simplest method of treating lead colic is to give a hypodermic injection of morphine, repeating it if necessary, and let the bowels take care of themselves. "The employment of cathartics," says Professor Flint,[1] "may be useful in removing lead contained in the contents of the alimentary canal. Aside from this object, and avoiding inconveniences from constipation, cathartics are not indicated." A free stool, however, would have a good moral effect on the patient, who is apt to regard the constipation as the sole cause of his trouble. And as it will be necessary

[1] Op. cit., p. 543.

to regulate the bowels in order to facilitate the elimination of the poison from the system while improving the patient's general condition, it is just as well to begin at once.

Many so-called remedies have been used in the treatment of this disease, including, of course, mercury and even general blood-letting. In 1752 Grashuis, a Dutch physician, conceived the idea that alum (sulphate of alum and potash, or ammonia) would be a good remedy in this disease on account of the sulphuric acid in it, which he supposed would combine with the lead and render the latter inert. This plan has since been followed by various physicians, and even at this time it is mentioned by some authors as a specific in this disease. For instance, Bartholow[1] says: "For the treatment of the colic of some cachexiæ the appropriate remedy for the cachexia will be necessary: for example, quinia in intermittent colic, iodide of potassium in nocturnal colic, and alum in lead colic." Usually about a drachm is given four times daily in water, and in about one week or more the patient may get better or not, which he generally does anyhow. A more preposterous plan of treatment cannot well be imagined. The same may be said of Epsom salts (sulphate of magnesia), which is undoubtedly an imitation of the alum treatment. The fact that Epsom salts contain sulphuric acid does not make it preferable as a saline cathartic in this disease to Rochelle salts. Both alum and salts frequently irritate the stomach, and the former not infrequently produces vomiting.

Instead of losing time with such doubtful, if not injurious means, I have used, with nearly invariable success, a combination of croton-oil and morphine in pill form, as has been suggested by various authors. I have usually ordered one to two drops of croton oil and one grain of morphine rubbed up with a sufficient quantity of extract hyoscyamus (or some inert extract), to be divided into three pills, one of which is to be taken every two hours until pain is allayed and the bowels move. Loomis[2] uses, in addition to croton oil and morphine, one sixth grain extract belladonna in each pill. The croton oil is ready to act about the time that the patient is getting relief from pain by the influence of the morphine, and both indications are thus met at the same time. There are other cathartics that might answer the same purpose if given with opium, but I have always found these pills to be of a very convenient form for administration, and they do not irritate the stomach. They are as certain a remedy for lead colic as quinine is for intermittent fever, and should be freshly made up. One or two are generally sufficient, and rarely have I found it necessary to give the third. Of course if the case requires it a hypodermic injection of morphine may be given at once, as has already been said. I have never had occasion to use it. I do not think that it would interfere with the early movement of the bowels, and if it did I do not believe that it would make any difference. Niemeyer[3] says that "there is no remedy more successful than opium in relieving the constipation of lead colic." A painter once informed me that whenever he found obstinate constipation and colicky pains coming on he would take thirty drops of laudanum. In this way he not only allayed pain, but soon had a copious evacuation from the bowels. By leaving off work for a couple of weeks he was ready to begin again. In that way he said he "kept out of the hands of the doctors."

The treatment should not end with curing an attack of lead colic, however, especially if the patient goes back to his occupation. The poison must be eliminated from the system, otherwise symptoms of chronic lead-poisoning will appear in time, if indeed they have not already commenced.

For eliminating the poison the only proper remedy is the iodide of potassium. This drug was recommended for the first time in this disease by Melsens, of Paris, in 1849. By chemical action it produces the soluble iodide of lead in the system, as already stated, and its undoubted efficacy is proved by the well-known fact that it causes lead to appear in the patient's urine.[1] I always give the iodide in ten-grain doses three times daily, and have never found it necessary to give it in larger doses. The question arises, How long should this remedy be continued? Where the case is not of long standing, and where paralysis has not occurred, I believe that six weeks is enough—it being understood that meantime the general health must be attended to, and that the patient does not continue to be exposed to the poison. For this reason he should at once leave off work and endeavor to find some other employment for the time. But where drop-wrist has occurred, I have kept up this treatment steadily for three months. Even in the worst cases I have never had occasion to use the iodide any longer than that if the patient obeyed instructions and took it steadily. I prefer to discontinue it then and put the patient on bark and iron. If necessary, however, the iodide may be continued for a longer period and in larger doses. I have never tried the sulphur baths and have never found them necessary.

Iodide of potassium eliminates lead from the system, but it does not restore the paralyzed and atrophied muscles to their normal condition. For this purpose electricity is the proper remedy, although dry-rubbing and otherwise stimulating the muscles meantime should be practised. At no time during treatment is the induced (faradic, which is subdivided into primary and secondary) current to be preferred to the constant (galvanic, continuous) current. At first the former is usually of no benefit, since in many cases it fails to cause the affected muscles to contract. In marked cases, where all other methods of applying electricity fail, *the interrupted constant current should be used, and if necessary the poles should be changed.* After considerable improvement has taken place the constant current without the interruptions may be used. The strength of the current should be about fifteen to twenty cells, according to circumstances.[2] If the interrupted constant current be used, the number of interruptions should be about six times a minute. Placing the negative pole over the musculo-spiral nerve in the arm (middle cervical vertebra—De Watteville) and the positive pole successively over the motor points (bellies) of the affected muscles of the forearm, the constant current, interrupted or not as the case requires, should be used for about two minutes for each muscle. As the case improves sufficiently the induced may be substituted for the constant current, although I have never seen any benefit derived from the change. The applications of electricity should be repeated three times a week (every other day) until a complete cure is effected.

If the interrupted constant current fails to cause the affected muscles to contract at first, even though the poles be changed, the prognosis is less favorable. Such cases appear to be rare, but even then a complete cure is not to be despaired of without further trial. The applications of electricity should be repeated. At the same time the iodide of potassium should be systematically administered with a view to eliminating the poison, and the general health should be attended to. If then the interrupted constant current failed to cause the muscles to contract, the case might be regarded as hopeless.

Of the twenty-six cases mentioned, only four had anything like a blue line along the gums. Dr. J. C. Mackenzie, of this city, saw most of these cases with me. I do not attribute the discoloration in those four cases to the sulphide of lead. One had lead tremor of the upper extremities. I only saw him once. There were seven who applied while they had lead colic, and they all recovered without difficulty. There were eighteen with lead paralysis to a greater or less extent. Of these two were affected only in the left hand, five in the right,

[1] Flint, op. cit., p. 544.
[2] De Watteville: Medical Electricity, second edition, p. 187. 1884.

and eleven had complete double drop-wrist. In those cases where one hand only was affected the paralysis was not so marked as in the cases of double drop-wrist, and in one case the index and middle fingers of the right hand were only affected, the former much more markedly. Of the eleven that had complete double drop-wrist, two were sent to hospital, not having sufficient means to be treated outside. One of these had tremor of the hands and atrophy of the thenar eminences. Of the remaining nine with double drop-wrist, eight were cured without difficulty, but in one case the interrupted constant current failed at first to cause the affected muscles of the right hand to contract. After three weeks' systematic administration of iodide of potassium and repeated applications of electricity they began to respond. The muscles of the left hand responded from the first. There was marked double drop-wrist and the muscles of the thenar and hypothenar eminences were much atrophied. This patient completely recovered after five months' treatment. Eight of the eleven cases having double drop-wrist stated that they noticed that the right hand began to weaken first, and generally attributed it to getting turpentine on that hand, while three did not remember which hand was affected first. Of seventeen cases of lead-poisoning during the past year reported to me by Dr. Edwin E. Swift, through the courtesy of Professor E. C. Seguin, of the Department for Nervous Diseases, Manhattan Eye and Ear Hospital, in this city, six had the so-called blue line along the gums; none were affected in the right or left hand alone; seven were not affected with paralysis; and ten were affected in both hands. Of these, four are reported as having had paralysis to commence first in the right hand and six doubtful. Adding these ten to my eighteen, we have twenty-eight cases of lead paralysis. Of these, seventeen were first affected in the right hand, two in the left, and nine were doubtful. Twenty-one cases were affected in both hands, and the remaining seven would doubtless have become so in time if they had not applied for treatment. In a total of forty-three cases there was a so-called blue line along the gums in ten, and none in thirty-three; a result likely to be found in an eqnal number of laboring people who had never been exposed to the influence of lead-poisoning.

I do not believe that there was any local effect of the poison on one hand in preference to the other. It may have been accidental that more were affected in the right hand than the left in the above-mentioned cases. Or it may be that most of them, being right-handed, merely noticed it in the right hand first, though it may have existed to some degree in the left hand also. For the same reason, left-handed people might be likely to notice it first in the left hand.

31 West Thirty-third Street, November 26, 1884.

A Reminiscence of the International Medical Congress.—On the first day of the great gathering, while the different nationalities were flocking into the University porch, they encountered on the steps a porter distributing small rectangular cards, the size and shape of book-markers. These were received by the English and Americans with an amount of laughter and merriment utterly unintelligible to their colleagues of the European continent. On these cards were printed the following:

W. C. Stinck's,
Bog Papir og Kunsthandel,
Amagertow 33,
Kjöbenhavn.

Translated into what Mark Twain calls "a language a Christian can understand," this announcement is a very prosaic one. The first line is the respectable shopkeeper's name, which in Danish has not its English meaning. The remainder is simply "Dealer in Books, Stationery, and Art, 33 Amager Market, Copenhagen."—*Med. Press.*

VOMITING IN PREGNANCY.

By W. GILL WYLIE, M.D.,

Professor of Gynecology in the New York Polyclinic, and Gynecologist to Believue Hospital, New York.

In the spring of 1879 I was studying diseases of the cervix uteri in preparing a paper upon "Laceration of the Cervix Uteri," and I came across Dr. Edward Copeman's paper in the *British Medical Journal* of May 15, 1878, on "Dilatation of the Os Uteri for Vomiting in Pregnancy." About this time I had two cases of vomiting with pregnancy, and had tried many drugs with poor success. One of these was a multipara, and I had very little trouble in introducing the index finger of my left hand into the os uteri up to the first joint, and it gave complete relief. The other patient was a primapara that I had treated for retroversion, and had become pregnant while wearing the pessary. Notwithstanding that the uterus was held in good position, the vomiting was very severe. The cervix was pointed, hard, and had a slight erosion of mucous membrane around the os. Without using great force I found that I could not pass my finger. I put her in Sims' position and with a uterine dilator opened the cervix by gradually dilating it for a half inch or more. There was slight pain and a little bleeding, but no real disturbance. The vomiting was somewhat relieved, but not cured. After an interval of four days I dilated the cervix again, going pretty well up to the os internum with the point of the dilator. After this the vomiting ceased. In the fall of the same year a case very similar to the latter came under my care; when I examined it I found the uterus completely retroverted and the fundus fixed under the ilio-synchondrosis; I replaced the uterus and kept it in position by a pessary; the backache and local pain were completely relieved, but the vomiting grew worse. After trying various remedies without material benefit, I dilated the cervix, and after the second dilatation the vomiting completely ceased. Since then, I have had many cases, some of them extreme cases; one where the patient was so ill that I was sent for to bring on abortion as the last resort, and in all relieved the vomiting by dilatation and local treatment, except in two instances, one a patient that left town after one dilatation, and the other was a hospital case, where the whole vulva and vagina were completely covered with inflamed and sensitive venereal warts.

Although vomiting in pregnancy is so common that it is one of the most reliable of all the early symptoms of pregnancy, after a close study of many cases I am convinced that marked vomiting in pregnancy is, in the majority of instances, due to an abnormal condition of the cervix uteri. The cervix may be the seat of acute disease, or the tissues are abnormal from previous disease or imperfect development of the cervix, and in the majority of cases the cause of the vomiting will be found in the cervix. Not long since a handsome, healthy young woman came to my clinic in great distress about her abdomen growing large—she had been married four or five months. She said she had not had her menses, but she could not be pregnant, for she had not had any morning sickness, and all her friends said it must be a tumor. On examination I found the cervix perfectly healthy, and the uterus enlarged as it should be in pregnancy at the fifth month.

Many women do not have nausea with pregnancy, and the absence of that symptom indicates a healthy cervix, and its presence I believe nearly always indicates local disease or an abnormal state, the result of disease or imperfect development.

In looking over the literature, it is surprising how little has been done in the way of local treatment, and how much women have been dosed with almost every kind of drug for it. To-day, in our best text-books on obstetrics it is not treated as a symptom indicating disease, but merely as one of the symptoms of pregnancy, and local

treatment may be referred to, but it is not advised. No one denies how serious it often is, and that now and then it causes death. In 1873 Dr. Alfred H. McClintock, in a paper read before the Dublin Obstetrical Society, in which he advocated induction of abortion as the only thing to do in extreme cases, says that without much trouble he had collected the record of fifty deaths from vomiting in pregnancy, and he reports thirty-six cases in which abortion was induced as a last resort, with twenty-seven recoveries and nine deaths; but he had nothing to say about local treatment.

In a paper before the London Obstetrical Society, in 1871, on "Vomiting in Pregnancy: Its Cause and Treatment," Dr. Graily Hewitt claims that the severe forms are due to local disease, but makes the mistake of attributing it all to his hobby—displacements, flexions, and versions.

In the London *Lancet* of February, 1878, Dr. M. O. Jones, of Chicago, Ill., wrote a paper on "Vomiting in Pregnancy," and advocated in certain cases the local application of nitrate of silver to the os uteri as a cure. In some cases this will undoubtedly stop the vomiting. Dr. Copeman's paper came out in the same year, May, 1878, in the *British Medical Journal*, and was followed by a number of articles and reports of cases confirming Dr. Copeman's views. In 1879, when Dr. Sims returned from Europe, I had two or three cases which I had him see as typical ones treated by Dr. Copeman's method of dilatation. In 1880 he wrote a paper on the subject, and it appeared in the *Archives of Medicine*. In my paper on "Laceration of the Cervix," read before the County Medical Society, 1881, under the head of Prevention, I said: "When a woman becomes pregnant it must not be taken for granted that the neck of the uterus is perfectly healthy, or if it is in good condition at this time, that it will remain so throughout pregnancy."

Morning sickness to a moderate extent may occur without any perceptible disease of the cervix, but, as a rule, it is a pretty certain indication that there is an unhealthy condition of the neck of the uterus. For two years past, I have not seen a single case of this distressing condition that did not yield in a few days to local treatment, while several of my cases were not helped by the usual remedies.

If, during pregnancy, there is nausea, leucorrhea, or any indication of disease of the cervix, an examination should be made and the case treated, not only to relieve the symptoms, but in order to get the neck of the uterus in a healthy condition before labor.

The danger of inducing an abortion by treatment is by no means as great as I at first supposed it would be, and I think that with reasonable care many more cases of abortion and premature birth could be obviated than would be caused by the treatment. Applications can be made to the cervix, and for at least three-fifths of an inch within the canal, and tepid vaginal injections can be safely used during pregnancy.

For the relief of nausea, I have found dilatation of the canal for three-fifths of an inch to be, so far, perfectly successful in relieving this symptom and in softening the hardened condition of the cervix so commonly associated with it, and perhaps causing the vomiting. Sometimes the index finger introduced to the first joint will answer, but in many cases, especially in primiparæ, it is very difficult to get even the point of the finger into the cervix. I now use a modified uterine dilator bent nearly at right angles, so that not more than three-fifths of an inch can enter the canal; it is opened by a screw adjustment which enables you to regulate the extent of dilatation, and its shape makes it easy to introduce it even when the cervix is, as it often is, very high and far back in the pelvis.[1] In some cases, there will be slight hemorrhage after even moderate dilatation, and usually one dilatation completely relieves all vomiting. After dilatation, the neck soon becomes shorter and much softer.

I caution my patients, when pregnant, to be careful at the time that they would expect to have their menses if not pregnant, and to be especially careful if any of the usual premonitory symptoms should become manifest; for I am satisfied that at this time abortion or premature labor is most likely to occur.

If not successful in correcting any trouble of the cervix, and there is any discharge, vaginal injections are to be used, and for some days before labor is expected antiseptic injections are used once a day. In all cases I have the nurse come early, and if these carbolized injections are not used before, one is given at the first indications of labor beginning, and everything must be in readiness for the carrying out of a somewhat modified form of Listerism during and after labor, until the discharge ceases. An examination is carefully made of the cervix and uterus before the patient is allowed to sit up. If obstetricians would take as much pains to prevent laceration of the cervix uteri as they do to prevent laceration of the perineum, much would be done toward obviating this accident. They should avoid rupturing the membranes until it is absolutely necessary. In a rigid os, carefully and slowly assist dilatation with elastic dilators. In dryness of the parts, freely use lubricants. When the pains are very powerful, and the voluntary efforts at expulsion violent, the latter should be controlled, if necessary, by chloroform at the time of the head passing the cervix, and one or more fingers be kept against the head, and an effort made to regulate and modify the more violent efforts at expulsion. Sometimes an opportunity will be found to help the cervix over a part of the head, where it is retarded more than at other points.

It is true that many cases of lacerated cervix give the history of forceps being used, but this may be due to the fact that those conditions which necessitate the use of forceps are often the same in which a laceration of the cervix would take place whether the forceps are used or not. To avoid lacerating the cervix by the use of forceps, it is well to dilate the cervix as much as can safely be done before they are applied, to decide as early as possible that forceps are necessary, and to handle them skilfully, adjusting them accurately, and pulling steadily and in the right direction and at the right time. Forceps, timely and skilfully applied in retarded labor, often prevent sloughing and some of the worst forms of lacerated cervix.

Anyone who has watched carefully the changes that take place during pregnancy, can readily understand that any condition of the tissues of the cervix which prevented its softening might cause reflex vomiting. A few weeks after impregnation the cervix becomes congested, is longer than normal, and bluish in color; by the second month the congestion is at its height, and the mucous membrane may be much softer than normal, but underneath it hard tissues may be felt, and the cervix is not completely softened until after the fourth month. In the later months it may be so soft as to make it somewhat difficult to define its outlines, and the os internum seems to be the only thing which prevents an escape of the contents of the uterus. A week or so before labor the cervix may be stretched and flattened to such an extent that it cannot be defined at all.

Infiltration, congestion, and swelling always precede this softening process, and if the tissues are imperfectly developed, or if they are indurated by disease, or left indurated after the disease has subsided, it is plain that the softening process cannot take place normally. If there is

[1] In my last instrument represented by the wood-cut, the screw is left out, as I find the hand a better guide as to degree of force needed to dilate.

cystic disease of the glands or follicles the softening cannot take place normally. If there is granular erosion, or hard cicatrices from laceration, or diseased everted tissue, it cannot take place normally. In cases of subacute catarrh, there is often hyperæsthesia of the mucous lining, and deeper tissues may be hardened and changed, and thus the softening process preparatory to enormous expansion cannot normally take place, and reflex vomiting is the result.

I admit that without further proof the above would not be convincing, but if the following plan of treatment is adopted, I am certain that nearly every case of vomiting, no matter how severe, can be cured without any special medicine being used by the mouth, except what may be needed to regulate the bowels and keep the general health good.

If a patient comes to me suffering from nausea and vomiting, and there are other symptoms of pregnancy, instead of dosing her, I make a local examination and give local treatment for any disease of the cervix that I may find. If there is no active disease I would dilate the cervix, knowing from experience how frequently it will give relief. The dilatation should not be made when the menses would be due, nor when any of the usual premonitory symptoms of the menses existed.

The vulva and vagina are carefully washed with a 1 to 3,000 solution mercuric bichloride, I then dip the blades of my dilator in pure carbolic acid and shake off the free acid and introduce the points into the cervix for about half an inch, and slowly dilate until the blades separate from one-third to one-half an inch. If there is an eroded or everted diseased tissue present, I touch it lightly with an applicator that has been dipped in pure carbolic acid. I then, with a powder-blower, cover the cervix with a thin layer of iodoform, and place against the cervix a flat pledget of borated absorbent cotton soaked in pure glycerine, which is to be removed in twenty-four hours by means of a short string attached to it. In some cases there is slight pain, but in most cases no pain or real disturbance whatever is produced. As a rule, this will relieve nausea; but after four or five days, if there is still nausea, I repeat the dilatation and may pass the dilator three-fourths of an inch, and in some cases where the cervix is long, even more. Very rarely will more than two dilatations be needed. In some cases the cervix is so patulous that dilatation may seem to be useless, but well up in the cervix tight bands may be found, and when stretched complete relief is effected. Even where the cervix is lacerated and apparently open, bands may be found, and when stretched relief is obtained. It is easy in such cases to recognize when the end of the dilator comes against the os internum, for it is firmly closed, and by passing the instrument until the os is felt and then slightly withdrawing it, dilatation can be done without much risk. In severe cases the cervix may be of a very bluish-black color. The glycerine application causes a free watery discharge and relieves this congestion. Formerly I used nitrate of silver for granular erosion, but I found that the carbolic acid and glycerine has an equally good effect.

If there is a doubt about the amount of dilatation, the best test is to put the patient on her back, and when the index finger, up to the first joint, can be easily passed into the cervix, the dilatation is sufficient. Before resorting to abortion in any case where dilatation up to the os internum failed, I would first dilate the os internum and wait long enough to see if it would stop the vomiting, for this can be done in some cases without abortion necessarily following.

Conclusions.—1. That nausea and vomiting, or morning sickness in pregnancy, should not be considered and treated as merely one of the symptoms of pregnancy, but, as a rule, as indicating an abnormal condition of the tissues of the cervix uteri, due to imperfect development, disease, or the effect of disease on the tissues of the cervix.

2. That any pathological state which interferes with the softening and other changes which the cervix undergoes during pregnancy, may cause nauseal vomiting.

3. That in most cases relief is obtained by freely dilating the cervix uteri below the os internum, and in many instances it is the only means by which relief can be had. It is true that inducing abortion will give relief, but to accomplish this the cervix must be dilated.

4. That in many cases specific medicines given by the mouth are useless, and, as a rule, should not be used until a local examination is made and the indications for local treatment ascertained.

THE LAW GOVERNING THE COMPENSATION OF PHYSICIANS.

By HENRY A. RILEY, ESQ.,

NEW YORK CITY.

THE usual and proper performance of the duties of a physician requires him to answer calls for medical services at times and under conditions when it will be impossible, unfeeling, or at least indelicate for him to stop to inquire who is to pay him for such services. This being the case, it often happens that the physician runs a great risk of losing all compensation whatever, owing to the lack of there being any person at once legally responsible and pecuniarily able to pay.

The legal questions at issue, and the cases decided in the courts on this subject, will be of general interest.

It will, however, be convenient to discuss only the question of the responsibility of a private person who requests medical services for some one else, and reserve until another time the consideration of the case where some public official requests the medical service, and the point is whether his request binds the town or county.

It may in general be stated, that a person who calls a physician to attend some one else is not liable for the physician's bills. The point in the cases almost invariably turns upon the question whether the person ordering the services acted for himself, or as agent for the sick person, and the view the physician took of the relation between them, by seemingly holding the one or the other liable.

The gist of the law of agency is well stated by Judge Daly, of the New York Common Pleas Court, as follows: "It is a general principle of the law of agency that one who procures services to be done for another, is not himself chargeable as the debtor, unless he omits to make known his principal, or erroneously supposes that he has authority, or exceeds his authority, or expressly or implicitly engages to be answerable either by directly promising to pay for them if rendered; or by doing or saying something which justifies the person who is to perform them in supposing that the one who applies to him engages to pay for them." Buck *vs.* Amidon, How Pr. Rep., 378.

An apparent exception to this rule, making the person receiving the services liable for them, is that of a person who requests the services for those whom he is under some legal obligation to support or care for, such as a husband or the father of minor children. The cases illustrative of these points will be instructive. In England, at least until recently, a physician could not collect by law from any one for his services, they being considered as rendered gratuitously without there was an express agreement to render compensation. A curious case showing this, is Vertch *vs.* Russel, 3 Q. B., 928, tried in 1842. The defendant here was a lady of moderate fortune, who requested a physician to attend her brother, who was ill and in indigent circumstances. It did not appear by the evidence that any agreement was made in advance in regard to the matter, but after a time she wrote him a number of letters in which are these expressions: "As your account against me for attendance upon my brother must be formidable, you will oblige me

by letting me have it." "My wish is to present you with some such a sum as you would call upon me to pay you." "I do not know what you would deem, under the circumstances, a suitable acknowledgment." "I hope you will at once tell me what sum will be agreeable to you to accept from me." The physician named £150, which the lady thought too much, and offered £70 in settlement. This amount was declined and suit brought for the larger sum. On the trial a verdict was given for the defendant, which was afterward affirmed. The ground of the decision was apparently that there was no original contract and the letters were not sufficient to take the place of such contract. From the rule preventing the physician from bringing suit without some agreement, it is clear that he would have had no cause of action against the lady's brother.

In Sellen *vs.* Norman, 4 Carr. & Payne, 80, another English case, where the services were rendered to a servant, it was said: "It seems that a master is not bound to provide a menial servant with medical attendance and medicines during sickness, but if a servant fall ill and the master calls in his own medical man to attend such servant, the master will not be allowed to deduct the charge for such medical attendance out of the servant's wages, unless there be a special contract between the master and servant that he should do so."

This case is an apparent exception to the general rule, owing to the relation of master and servant. This relation in this country is not regarded in quite the same light as in England, and it is a question how the courts here would decide the point: there do not seem to be any cases bringing it up.

In Boyd *vs.* Sappington, 4 Watts, 247, a Pennsylvania case tried in 1835, there was a request by a father to a physician to attend his son, the words used being: "Doctor, you must come, I am afraid my son will die."

It appeared by the testimony that the son was thirty-two years of age, and in business for himself. The court held that this request raised no implied promise on the part of the father to pay for the physician's services. If a stranger had called the doctor it would have been a parallel case with that of an inn-keeper, who might summon a physician hastily to attend a sick guest, and such a person would not be liable. Under the circumstances the court held the rule to be the same as if the father had been a stranger. It was said "a different principle would be very pernicious, as but very few would be willing to run the risk of calling in the aid of a physician where the patient was a stranger, or of doubtful ability to pay."

In Smith *vs.* Reddick, 5 Jones L., 342 (North Carolina), the plaintiff brought suit for services as a physician, rendered at defendant's request to a third person, under these circumstances: Reddick was not related, it would seem, to the sick person, but was sent by him for a Dr. Pettis, but not finding him, called upon Dr. Smith, and said: "I have come after you to go and see a sick man." Reddick did not return to the patient's house. The court said "the evidence tended to show that the plaintiff was aware of the fact that the defendant acted merely as a messenger, and did not intend or expect to make himself personally liable for the services which were to be rendered to the sick man. The doctor who was in attendance explained to the sick man, in the presence of the plaintiff, what had occurred, that the defendant, who had been sent for Dr. Pettis, not finding him, as the case was urgent, had applied to the plaintiff to come in his place, and the plaintiff would assist him in performing the operation, which was assented to. If the plaintiff was not willing to assist at the instance and on the credit of the sick man, it was his duty to have made known his objections. To hold the defendant liable under these circumstances, would deter every one from doing the charitable office of going after a doctor for a sick neighbor."

In Buck *vs.* Amidon, 41 How. Pr. Rep. (New York), 370, we find an instructive case. The plaintiff was a distinguished surgeon of New York City, and the defendant a well-known business man, also of the same city. The latter received a telegram from his brother at Groton, Conn., saying that a surgeon must at once be sent up, as a dangerous operation had to be performed, and requesting Dr. Buck's services. He then went to see Dr. Buck, showed him the telegram, urged him to go, secured his consent, met him at the railway depot, and accompanied him. The operation was very skilfully and successfully performed, and when asked for his bill Dr. Buck presented his charge of $400, in the name of the sick man. The patient expressed his surprise at the amount, and a short time afterward payment not being made, Dr. Buck wrote to him as follows:

"MR. J. C. AMIDON, Groton, Conn.:

"DEAR SIR: After waiting a reasonable time without hearing *from you*, I beg leave to remind you that it is customary to settle such accounts as mine, for professional services rendered at a distance, promptly. Hoping it will receive your early attention, I remain," etc.

The bill remaining unpaid, Dr. Buck brought suit not against J. C. Amidon, but against his brother, who had called at his office and requested the services. Dr. Buck testified on the trial that on his arrival at Groton, he had noticed the plain way of living shown by J. C. Amidon, and said he felt surprised that persons in such circumstances should think of sending to New York for a surgeon. These circumstances were introduced to show that the patient was originally regarded by Dr. Buck as his debtor. Suit was nevertheless brought against his brother, and the jury gave a verdict to the plaintiff for the full amount claimed. This verdict was, however, reversed on appeal, the court holding that it would be "preposterous to say, that a person who brings a message to a surgeon from the attending physician of a patient, requesting him to come and perform an operation upon the patient, is by the mere delivery of such a message, chargeable with the obligation of paying the surgeon for his services. He is a mere agent and nothing more, unless he communicates the message in such a way, or does or says something that fairly warrants the surgeon, before he undertakes the service, in supposing that he is the person who is to pay for it, and in this respect it can make no difference that the bearer of the message happens to be a brother of the patient." The case of Crane *vs.* Baudouine, 55 N. Y., 256, occurring in 1873, is a case in the New York Court of Appeals, and is the most authoritative statement of the law as it is in the State. The circumstances were as follows: Mrs. Martine, the defendant's grown-up daughter, was removed from her own house to be under her mother's personal care. Shortly afterward, as the plaintiff testifies, Mr. Martine called and said that the defendant (Mr. Baudouine) wished him to call and see his daughter. Dr. Crane did so, and saw the defendant each day during his visits, left directions as to the proper treatment with the defendant, and told him what to do. He further testified that he did not know that Mrs. Martine was married until a considerable time after he began his visits, and that he charged the defendant on his books and sent him a bill. The defendant denied that he had ever employed the plaintiff or requested any person to call on him. The referee before whom the case was first tried, decided in favor of the defendant. This judgment was reversed on appeal, but on a second appeal the original judgment was affirmed. It was held, that the daughter being married and with a home of her own, had no claim upon the father, and that the fact of removal to his house for better care did not cast any obligation of support upon him. The father would, moreover, be naturally interested in the condition of his daughter, be ready to receive directions as to treatment, and would be likely to repeat to others what the physician might have said; but none of these things would warrant the implication of a promise to pay for the medical services, unless the defendant was under some legal obligation to care for the patient. It is said that the "acquiescence of one in the rendering of

service or benefit to another, not entitled to call upon him therefor, is not equivalent to an acknowledgment that it is rendered at his request. So far as a legal responsibility was concerned, the defendant, though the father of the patient, was a stranger to her and her necessities."

Perhaps the only case sustaining the opposite view here presented is Bradley *vs.* Dodge, 45 How. Pr. Rep., 57 (New York), where the following principle is enunciated: "Where a person calls at the office of a physician, and in the absence of the latter leaves his business card, written on it, 'Call on Mrs. Day, at No. 769 Broadway,' and leaves the card with a clerk in the office with a request to hand it to the physician and to tell him to 'come as soon as possible,' he becomes liable to pay the physician's bill in attending upon Mrs. Day in pursuance of such message." This case was decided before that of Crane *vs.* Baudouine, 55 New York, 256, and in an inferior court, so it can hardly be considered the law in New York State. The case, moreover, enjoys the very unusual distinction of being assailed by the court reporter as bad law in a vigorous note, from which we take the following extract: "Let us see how this thing works: we will take as an illustration an almost every-day occurrence arising in the country.

"A. B. is taken suddenly and seriously ill in the night-time and sends to his neighbor, C. D., living in the next house to his, to have him go after the doctor as soon as he can, for he is in great pain and distress. C. D. jumps out of bed without hesitation and hastily dresses himself, and goes out to his barn and takes a horse from the stable, and not waiting to put on a saddle or bridle, jumps on to the horse with the halter only, puts him at full speed for the doctor's office, some two or three miles distant. On arriving there he finds the doctor absent from home, but his clerk is there, and C. D. at once says, 'Tell the doctor to call on A. B., who has been taken suddenly sick; tell him to come as soon as possible.'

"In accordance with this message the doctor calls upon A. B., and prescribes for and attends him professionally for several days. After a reasonable time the doctor sends in his bill to A. B., and it not being paid as soon as the doctor desires, he calls on C. D. and requests him to pay the bill. C. D., with perfect astonishment asks why he is to pay it. The doctor informs him that he made himself liable to pay the bill because, when he delivered the message, he did not tell the clerk that he came for the doctor by the request of A. B., nor that he acted as agent of A. B. in delivering his message. 'Well,' says C. D., 'the fact was I did go at the request of A. B., and merely acted as his agent in delivering the message, and I will swear to these facts if necessary.' The doctor insists that it will do him no good if he should give such testimony, for the law is settled on that point, as just such a case has recently been decided in New York under just such a state of facts, where the jury in the Justice's Court found a verdict for the doctor for the amount of his bill, and on appeal by the defendant to the General Term of the New York Common Pleas, that court unanimously sustained the verdict of the jury and affirmed the judgment of the court below. 'Well,' says C. D., 'if that is the law, I think I will wait a while before I go after a doctor again as an act of neighborly kindness.'"

In recapitulation it may be said, that the nearly unanimous testimony of the law-books is to the effect that a person who requests a physician to render medical services to another does not himself become liable for the physician's compensation, unless he promises to make such compensation before the services are rendered, or unless he is under some legal obligation to care for the person in whose behalf the services are rendered.

Hydrochlorate of Cocaine.—Want of space has crowded out several interesting items concerning the use of this drug in dentistry, minor surgery, and laryngology.

Progress of Medical Science.

Changes of Hæmoglobin.—In a memoir on the substances which change hæmoglobin, and especially those which convert it into methæmoglobin, Dr. Hayem arrives at the following conclusions: Hæmoglobin gives the blood its characteristic redness, preserves its respiratory capacity, or, in other words, its property of absorbing oxygen, so long as it is not chemically changed. The most complete chemical change it can undergo is conversion into methæmoglobin. This substance is of a brownish color. When shaken in contact with air it does not absorb oxygen. Potassium-ferrocyanide and potassium-chloride both convert hæmoglobin into methæmoglobin; these substances have been used for many years therapeutically; recently nitrite of amyl and nitrite of soda, which have also this property, have been employed. Hayem proposed to ascertain how it is that considerable doses of these medicines can be administered without leading to a change in the hæmoglobin; also, when it does undergo an alteration, and death does not result, by what process the blood is freed from the methæmoglobin. Although hæmoglobin dissolved or rendered soluble by the coagulation of blood has the same respiratory capacity as the hæmoglobin of blood-corpuscles, there is an important difference in behavior between these two varieties in presence of the substances which provoke the formation of methæmoglobin. The hæmoglobin of red blood-corpuscles is indifferent to the action of those substances which convert dissolved hæmoglobin into methæmoglobin. Submitted to the influence of nitrite of amyl vapor, the hæmoglobin of blood-corpuscles is rapidly converted into methæmoglobin, which reabsorbs oxygen; whereas dissolved hæmoglobin, converted into methæmoglobin, is permanent, and persists until the blood putrefies.

Weigert's Method of Staining the Brain and Cord.—A solution of hæmatoxylin is prepared with water and alcohol. The sections are kept immersed in it during an hour, and the temperature is maintained between 104° and 122° F. They are then removed from the solution, washed, and placed for three hours in a two per cent. alkaline solution, or in one of potassium ferrocyanide. Afterward they are submitted to the influence of alcohol, xylol, and Canada balsam as in the usual method. In sections thus prepared, nerve-fibres with a myeline sheath are stained blue, the neuroglia pale yellow, and the ganglia cells brown. This method throws into relief the nerve-fibres with a myeline sheath. In preparations of tabes dorsalis, Clarke's columns appear as light rings against a dark background; microscopic examination shows that a large quantity of nerve-fibres with a myeline sheath have disappeared.

The Treatment of Acne in the Male by the Cold Urethral Sound.—Dr. Sherwell, of Brooklyn, believes that acne and rosacea, either alone or combined, depend in almost every instance upon conditions reflected from the sexual or digestive apparatus, and in the relative order as given; and that even the red face and nose of the coachman, of whom Hebra speaks, are only intensified, not created, by the external irritation of biting winds, etc. His theory of the etiology of the more pronounced forms of acne, as the tubercular variety, and rosacea, is that nine out of ten cases are caused by congestion of the mucous membranes of some of the viscera spoken of, probably passive in character. Why they should be reflected upon the face he does not know, and can form no opinion, any more than he can in urticaria, which arises, in his belief, from a more active and ephemeral but similar condition of the gastro-intestinal mucous membrane in the same relative number of cases. He thinks it probable, however, that the mucous irritation and consequent congestion is situate higher up in the alimentary canal in urticaria. In these cases, too, it

might be difficult to explain why the efflorescences are almost always situate on the trunk and limbs. It will be seen in the foregoing how far he is removed from the Marsyan-like dogma of the Viennese school, and not alone in respect to these diseases, but in regard to others, as, for instance, eczemas of the infant or child; in those cases he pays quite as much attention to the primæ viæ as to the skin, considering the trouble as springing very often, if not generally, from gastro-intestinal irritations. In short, he believes in the complete analogy between the skin and mucous membranes, and thinks their reflected action is much more common and important than many authors would have us believe. He recommends in persistent cases of acne and rosacea in the male subject, the use of the cold urethral sound, and that too with some degree of diligence. He does not, of course, mean by this that proper topical measures to the parts affected are not to be used in conjunction therewith; or that tonic, cathartic, dietetic, and hygienic measures and principles to meet common-sense indications should be omitted.—*Journal Cutaneous and Venereal Diseases*, November, 1884.

Elephantiasis Scroti.—A tumor of the scrotum, weighing forty-two pounds, was successfully removed at the Prince Alfred Hospital, Sydney. The patient was a white man, twenty-four years of age, with a good family history. He had resided where elephantiasis is unknown. At the age of six years, an enormously hypertrophied prepuce was removed. At the age of twelve years he received a blow on the scrotum, followed by a painless enlargement, and at the same time he had an attack of chyluria. From this time on there were frequent febrile attacks, chyluria, and gradual increase of the tumor, until the penis was lost to view. Urinary sinuses were also formed. Repeated examination of the blood showed absence of filariæ. Leucocytes, however, were in excess, and the red corpuscles appeared swollen and did not form rouleaux. The operation left both penis and testicles, and was accomplished with little loss of blood by the use of Esmarch's roller and india-rubber compressor. The tumor was composed of dense white fibrous tissues, interspersed with patches of adenoid growth. It contained numerous enlarged blood-vessels, and dilated lymph channels. There were patches of thickened horny epidermis, excessive deposit of pigment in the rete, and the stratum granulosum was increased in thickness.—*Australasian Medical Gazette*, June 15, 1884.

The Relations of Hysteria with Scrofula and Tuberculosis.—Professor Grosset, of the Montpellier School of Medicine, concludes a series of articles on this subject (*Brain*, part xxvi., 1884) by the following summary: "Tuberculosis, like all other diatheses, is an essentially general and constitutional disorder; pulmonary phthisis is but one of its manifestations. It may show itself as a neurosis, and more particularly as hysteria. Just as chorea is often a rheumatic disease, angina pectoris a gouty disease, thus hysteria may be a tubercular disease, taking the word tubercular in its nosological, not in its anatomical sense. In speaking of hysteria as a tubercular disease, therefore, we do not assume the existence of tubercular matter in the nerve-centres, for we do not look upon tubercles as pathognomonic of the diathesis, which exists without them, as they may exist without it. The tubercular diathesis is essentially hereditary, but may be understood only if it be followed up in families under its various manifestations from generation to generation. We then see how hysteria may represent diathesis in one of the members of the family as meningitis may do in another, or Pott's disease in a third. Besides such cases, in which hysteria is the sole manifestation of the diathesis, there are others where the same individual presents, simultaneously or successively, the two orders of manifestations, pulmonary and neurotic. We then witness the typical phenomena which characterize other Protean diseases; the two orders of symptoms alternate and replace one another; or if they be simultaneous, influence and modify one another, until one of them gets the upper hand. In other words, the mutual relations between the phthisis and hysteria of the tubercular diathesis are like those between the cerebral and abdominal symptoms of typhoid fever, or between the visceral and articular manifestations of gout. These remarks concerning hysteria and phthisis form but a fragment of a great and true chapter concerning the relationship of all neuroses, and even of all nervous diseases, to the diatheses and general diseases. If we cannot understand the neuroses without perceiving their mutual relations, if the consideration of the '*neuropathic family*' is indispensable for securing a clear grasp of the phenomena of neuropathology, it is yet necessary to go still further and complete all this by the conception of the '*diathesic family*,' outside of which we shall find nothing but isolated, scattered, meaningless units. Hitherto the neurotic element of hysteria has much too exclusively attracted attention; the diathesic element has not been met by treatment. Though we have no specifics against diatheses (except in the case of syphilis), we nevertheless have various rational means to deal with them. The treatment of rheumatism is not that of scrofula, nor that of tuberculosis. Hence, it is not indifferent to know whether a neurosis depends upon the one or the other constitutional state. Three categories of indications will have to be fulfilled in the full treatment of hysteria. First, the actual symptoms are to be met with appropriate measures, such as ovarian compression, ether inhalations, æsthesiogenous applications, etc. Second, the state of the nervous system, which is to be modified at any cost: hydrotherapy is often useful; change of surroundings; electricity, galvanic, but more especially static. We have little faith in the bromides. Third, the diathesis forms the fundamental ground for a chronic exhibition of arsenic, sulphur, alkalies, chloride of gold, mineral waters, etc. Unless these three orders of indications be duly taken into account, our measures, based upon a superficial diagnosis, must necessarily remain sterile."

Rational Treatment of Typhoid.—Dr. Réal, under the above title, describes in *L'Union Médicale*, September 28, 1884, a method of treating typhoid fever, which consists principally in the administration of large doses of subnitrate of bismuth. He claims that it disinfects the intestinal canal, and prevents putrefactive changes by fixing the sulphuric acid, free or nascent, and changing it into an insoluble, inoffensive, black sulphate. Any substance employed to prevent or destroy putrefaction in the intestinal canal must be a powder insoluble in the digestive tract, inoffensive in itself, but having a real chemical action on the putrid matter. The subnitrate of bismuth he has found to fulfil these conditions better than any other agent. He administers it as follows: The first day he gives a starch clyster containing two and a half drachms of the bismuth, and by the mouth, from five to six drachms within an hour in divided doses. The second day this same quantity is given by the mouth, but the doses are extended through the twenty-four hours. This is continued daily until toward the end of the treatment, the dejections, becoming less and less black, contain particles of the white bismuth, when the daily dose can be gradually decreased. The diarrhœa is usually arrested. If constipation exists, sulphate of soda in doses of ʒ ij. to ʒ iv., by the mouth or rectum, may be given. He cites three successful cases in children where he has employed this treatment.

Psyche-ology.—One day last summer two boys were rowing past the Riverside Hospital, on Blackwell's Island. As they passed close to the Board of Health boat lying at the wharf, one of them rested on his oars, and spelling out her name, P-s-y-c-h-e, pronounced it "fish." "That don't spell 'fish,' you great idiot," shouted the other, "that spells 'Physic;' it's the doctor's boat."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 6, 1884.

RECENT CONTRIBUTIONS TO GASTRIC PATHOLOGY.

A NUMBER of contributions have of late been made to the subject of gastric disturbances. It was in 1878 that Leube first (after Beard) called attention to the subject of nervous dyspepsia, so-called; and a little later Julius Glax and R. Burkart wrote monographs regarding it. Leyden and Krafft-Ebing have also called attention to certain gastric neuroses found in spinal irritation and as the result of onanism. Quite recently Leube, at the meeting of the Congress of Internal Medicine, brought up the subject of nervous dyspepsia again, and both he and Edinger have made important contributions to the methods of diagnosis. Clifford Allbutt's Gulstonian lectures are most suggestive as regards the subject of gastric neuroses, while very recently Bouchard, Sée, and Mathieu have written upon gastric dilatation, and Glazinski and Jaworski have made an interesting preliminary communication upon the physical methods of diagnosticating stomach disease.

A perusal of the various communications above referred to leads to the impression that great strides have been taken in gastric pathology during the last five years. But it is equally certain that almost no definite and fixed results have yet been obtained. It would be useless to attempt any generalization, therefore, as regards the present state of our knowledge of the pathology of the subject. We shall, however, present to our readers an analysis of some of these later contributions since they show that certain lines have been laid down, working along which, pathology will in no long period of time reach something positive as well as practical.

Professor Leube's paper (*Centralblatt für Klinische Medicin*, January 5, 1884), in which he lays down rules for the examination of the stomach contents, has already been given in substance in this journal.[1]

A preliminary contribution covering similar ground, by Drs. A. Glazinski and W. Jaworski, of Cracow, has appeared in the *Berliner Klinischer Wochenschrift* of August 18, 1884. These authors have made examinations of the action of the gastric juice in two hundred cases of health and disease. Their method was as follows: the person experimented upon, having fasted till the stomach was empty, is given the white of a hard-boiled egg and 100 c.cm. of distilled water. He then remains quiet for an hour and a quarter.

At the end of this time, by means of a soft syphon tube, 100 c.cm. of water are introduced into the stomach, and the whole contents syphoned out and preserved for examination. More water is then introduced and removed in order to be sure that nothing remains in the stomach cavity. If the digestion was healthy the following conditions were found:

1. No pieces of albumen were returned through the syphon.

2. The stomach juice is clear or opalescent. It is neutral or feebly acid in reaction, and contains, as shown by methyl-violet, no hydrochloric acid.

3. The filtrate gives none of the reactions for syntonin or peptone. On the addition of a little hydrochloric acid it digests, in less than seven hours, a very small piece of albumen.

4. Under the microscope the fluid withdrawn shows no ferment-organisms or free nuclei.

If, despite the fact that the foregoing conditions are found, some dyspeptic trouble is complained of, a second examination is to be made, but in this case, only half an hour after the ingestion of the albumen. In healthy stomachs at this time the following ought, according to our authors, to be found:

1. About half of the albumen comes away with the fluid, and the pieces will be found swollen and their borders frayed.

2. The filtrate is strongly acid and shows the presence of HCl. It also shows the presence of syntonin and gives a moderately strong reaction for peptone.

3. The filtrate digests albumen without the addition of any acid.

4. Under the microscope no ferment-organisms or free nuclei are visible.

On the other hand, in pathological conditions it is found:

1. That the albumen ingested remains in the stomach much longer than an hour and a quarter, and this is what most frequently occurs. Sometimes the albumen is swollen and partly digested; at other times, when the gastric juice is absent, there is hardly any change.

2. The stomach contents are cloudy, of a yellowish-green or bluish color, and mixed with greenish-yellow flocculi.

At the end of half an hour the stomach contents are sometimes much more strongly acid, sometimes less acid than normal. After an hour and a quarter, the filtrate, if any albumen is present, is usually more acid than normal. After half an hour the filtrate may or may not contain peptone. After an hour and a quarter the fluid contains peptone. Microscopic examination shows the presence of mucous corpuscles colored with bile-pigment and ferment-organisms, or free nuclei.

The authors advise that after examinations have been made in the manner laid down by them, tests of the vital capacity and contractility of the stomach according to the method of Jaworski should be made. If no physical signs of disturbed digestion exist, then the gastric symptoms must be referred to a nervous basis.

The article of Leube upon nervous dyspepsia, read at the Congress of Internal Medicine, has been given in de-

[1] THE MEDICAL RECORD, April 12, 1884, p. 405.

tail in THE RECORD (May 31, 1884, p. 621). The attempt to give to nervous dyspepsia a distinct nosological status was not received with favor, and it may be stated that German writers generally show an inclination to abandon the term nervous dyspepsia for a broader one.

The article by Professor Bouchard is in the form of a lecture delivered before the Hospitals Medical Society of Paris on June 13th, and is most suggestive. He claims that gastric dilatation is of very frequent occurrence. Indeed he finds it in one case out of three. But the main part of his paper is devoted to an attempt to explain the so-called reflex phenomena of dyspepsia as well as many of the concomitant symptoms, by assuming that the fermenting food generates poisons and causes a true toxæmia.

In dyspepsia then we must look out for a toxæmic condition, just as in renal disease we must watch for uræmia. This view, which was suggested first, we believe, by Senator (*Berliner Klinischer Wochenschrift*, 1868, No. 4), is based by its author on a study of two hundred and twenty cases. It is in harmony with the present tendency of pathologists to reduce to the minimum the reflex and sympathetic processes as causes of disease.

An important contribution to gastric pathology has been made by Professor Germain Sée, and Dr. Albert Mathieu in the *Revue de Médecine*, Nos. 8 and 9, 1884.

These writers treat of atonic dilatation of the stomach, which they consider as does Bouchard, to be a very common condition. They believe also that many of the cases of "nervous dyspepsia," as described by Leube, should really come under this head. Atonic dilatation is not produced by mechanical distention, as is usually stated, but rather it is the result of an adynamic state of the general system. The pathology of gastric dilatation is thus comparable to that of certain forms of cardiac dilatation. Both are expressions of myasthenia. During and after adynamic fevers, or as the result of profound anæmia, or in conditions of mental depression, gastric dilatation occurs. Psychical causes are quite prominent in this affection, ranking only second in frequency. MM. Sée and Mathieu give an elaborate array of cases, and discuss the symptomatology and diagnosis.

The chief symptoms are flatulence, pains, vomiting, constipation, dyspepsia, and reactive effects upon the general system.

In the matter of diagnosis the authors are inclined to treat with derision some of the "fantastic" methods of physical exploration suggested by the Germans. Careful comparative examinations by percussion, after the introduction of effervescing powders, and then of pure water, are specially recommended. Percussion without these measures cannot of itself decide the diagnosis. Auscultation and succussion furnish also some corroborative signs. For the many details of this valuable paper, however, we must refer our readers to the originals.

TETANUS INFANTUM.

IN considering the comparative frequency and great fatality of the first kinesio-neurosis of life, it seems strange that we have not more definite and satisfactory knowledge of its etiology. The mere fact that many very diverse causes have been given by good observers shows pretty conclusively that no one of them is always operative. The most satisfactory way to reach a correct conception of this peculiar condition is first to consider the nervous status of the infant in general, and then in each case to carefully seek out the immediate irritant. What, then, constitutes the physiological predisposition to this severe and fatal tonic spasm of early infancy? The peculiar anatomical arrangement of the nervous system at the beginning of life is well known, and explains the physiological phenomena seen at this time. Although the brain is comparatively large in size in proportion to other organs, its condition is immature. It is soft from the immense amount of water it contains, light in color, with the gray substance and convolutions undeveloped. As a result the functions of the cerebrum are largely in abeyance. The spinal cord, on the other hand, the first formed nervous structure of the fœtus, has at birth a large development and a marked functional activity. As reflex action is one of the principal characteristics of the cord, it follows that in early life this kind of activity must overshadow all voluntary forms of motion. Moreover, at this time reflex action is not strongly held in check by cerebral inhibition. As the infant grows and the gray matter and convolutions become more developed, its nervous system reaches a condition of more stable equilibrium; but during the first days of life, with active, readily irritated spinal centres, and a watery brain incapable of much controlling energy, the only wonder is that reflex motor disturbances are not more frequently seen.

There are many ways in which irritants may act on the unstable nervous system and produce a tetanus. In this affection, as in eclampsia, the source of disturbance must be carefully sought out and, if possible, removed. Irritation and inflammation of the umbilical vessels or umbilicus have frequently been noted by different observers. Sometimes retained meconium in the intestines appears to be the source of trouble. A condition of personal and domestic filth, the infant being allowed to remain surrounded by its fermenting excreta, or even impure air and various atmospheric disturbances, have seemed to be sufficient to upset the impressible nervous system of the young infant and bring on a tetanic spasm. Sometimes violence to the cerebro-spinal axis during parturition is the starting-point of trouble; in other cases meningitis may be found. One of the late ideas is that an adherent prepuce may be a factor in causing the disease. There are thus many general and local agencies that, under favorable conditions, are capable of acting on the easily excited spinal cord and motor nerves, to the production of general or partial tetanus. Perhaps the most remarkable contribution to the literature of this subject appeared in 1846, in an article by Dr. J. Marion Sims in the *American Journal of the Medical Sciences*. This distinguished writer then first advanced the idea that tetanus was caused by a centric disturbance due to pressure from an inward displacement of the occipital bone. This displacement may at times be very considerable; again it may be so slight as to require careful examination for its detection. The pressure exerted by the occipital or parietal bones extends itself on the pons, medulla oblongata, and cord, with a resultant spasm. This explanation of the phenomena of infantile tetanus did not at the time meet with a favorable reception by the profession, and has since been almost forgotten. There has lately

appeared a monograph by Dr. J. F. Hartigan, in which the original views of Dr. Sims are again advanced and fortified by cases and autopsies. Histories are given of forty-nine cases in all, some seen before and some after death. Six of these cases that were seen early recovered under postural treatment. In twenty-five cases autopsies were made, in which a generally uniform post-mortem condition of congestion and extravasation of the brain and cord was found. No other internal lesion was observed except at times an engorgement of the lungs. Finally, eighteen cases are given in which a history was obtained after death, although some were seen before the fatal result, but where post-mortem examination was not allowed. One factor in connection with all these cases that the author especially brings out is that there was very generally found a depression of the occipital bone. The relation between the arrangement of the bones externally and the extravasation found internally at the autopsies, has afforded occasion for generalizing as to cause and effect, also to confirm the idea advanced so long ago by Dr. Sims. If we have here the only true pathology of tetanus infantum, the treatment of this fatal malady will be simple and frequently successful. Although a depressed occipital bone is physiological during the parturient state, if it persists after birth it soon becomes pathological, and must be relieved by reducing the displacement and thus saving the cerebro-spinal axis from injurious pressure. Unfortunately, however, while literary medicine is often so beautifully exact and satisfactory, clinical medicine is full of doubt and perplexity. Many excellent observers have not been able to discover any noticeable displacement of the occipital bone at the beginning of the disease, and if seen later it may sometimes be simply the result of brain shrinkage accompanying the rapid general atrophy. The tetanic spasm, by greatly interfering with respiration and circulation, would naturally produce the congestions and ecchymoses found on post-mortem examination in the cerebro-spinal axis and lungs. Doubtless a primary inward displacement of the occipital bone may at times be the first source of trouble. We think, however, that in tetanus infantum different cases may have widely different causes. When we remember the favorable development of the infant's nervous economy toward such an accident, varying doubtless in different individuals within wide limits of susceptibility, it seems scarcely probable that only one universal cause is always operative. Any injury or trauma should rather be looked upon as a possible exciting cause and endeavor be made to remove it. Certainly the medical treatment of this disorder is extremely unsatisfactory.

ARTIFICIAL HYPNOTISM IN PHYSIOLOGY AND THERAPEUTICS.

The so-called mesmeric sleep—artificial or induced hypnotism—although it can scarcely be said as yet to have found a well-recognized place in the domain of either physiology or practical medicine, and though still looked upon with disfavor and contempt by very many in the profession, is being made the subject of earnest study—as it was by the late Dr. Beard in this country—by several eminent physiologists in England and on the Continent.

Dr. Langley, of London, has written a very entertaining and scientific article on the subject in the *Popular Science Monthly* (October, 1884); the late Professor Laségue, of Paris, was an accomplished hypnotist, devoted much attention to the subject, and used to turn it to account in the treatment of his hysterical patients; Emile Yung, who has lately written a very entertaining book on "Normal and Pathological Sleep," has a long chapter on mesmerism, in which he details the advantages which may be derived from it in hysteria; Charles Richer, in his "Clinical Studies in Hystero-Epilepsy," speaks highly, as a means of treatment, of "Braidism" (so named because Braid, of England, in 1843, was the first to give this artificial sleep a scientific exposition); and Heidenhain, of Breslau, has experimented much in hypnotism and written much about it.

At a recent meeting of the French Association for the Advancement of Sciences, Dr. Bernheim, of Nancy, well-known as a clinician and the author of a work on practical medicine, read a report of three cases of chorea cured by what he calls "the hypnotic suggestion." He remarks that "suggestion" in the hypnotic state may "realize" (cause) paralysis, contraction, anæsthesia, and divers functional troubles, and that it is natural to demand if this same "suggestion" may not in certain cases cause such functional troubles to disappear. Dr. Bernheim affirms that for many years he has obtained a great variety of excellent therapeutic effects, and often substantial cures by the "suggestive" method, "which consists, during the provoked sleep, in affirming the disappearance of the different subjective symptoms experienced by the patient."

Drs. Heurot and Voisin, at the same meeting, related cases in their practice where they had derived benefit from "suggestion." Voisin's patient was a female, "debauched, coarse, and lazy." He utilized the hypnotic sleep "to calm this hyper-excitation, mental and sensorial!" During the mesmeric sleep—which he kept up for from ten to twelve hours a day—he improved the opportunity to *suggest* to the patient "ideas of obedience, of submission, of decency, and exhorted her to useful labor." He also encouraged her to learn by heart entire pages from some moral book. "A complete transformation was effected in several months!"

Whether or no, in accordance with the above example, it shall yet be found that the best way to reform the immoral and criminal class is to *hypnotize* them and "suggest" morality, subordination, and decency, remains for future sociological experimenters to decide.

Dr. J. N. Langley, in the *Popular Science Monthly*,[1] who thinks that "there is no doubt that mesmerism may help and sometimes cure persons suffering from certain diseases of the nervous system," ably treats the subject from a physiological standpoint. He thinks that "as disease may be the result of either over-activity or of under-activity of any part of the central nervous system, it is reasonable to suppose that a beneficial effect will follow the employment of a method which allows us to diminish or increase this activity at will." This is, he thinks, a side of the question "which is of the greatest interest both to physicians and to physiologists, since it bears directly upon the problem of the influence of the

[1] Popular Science Monthly, October, 1884: The Physiological Aspect of Mesmerism.

nervous system on nutrition. "There is good reason to believe that, by directing attention strongly to any particular part of the body, the nutritive state of that part of the body may be altered. The determination of the actual way in which this is brought about is full of difficulties, but the following way is, at least, theoretically possible. It may be that the nerve-centres connected with the tissue in question are made unusually active, and that they send out nerve-impulses of a trophic nature, that is, impulses which directly control the nutrition of the tissues. The alteration in the tissue caused by its changed nutritive state—its changed metabolism—may conceivably be beneficial or detrimental to the whole organism; it may give rise to a diseased state, or get rid of an existing one."

This writer's explanations of the phenomena of hypnotism are summed up in the following propositions: "The primary condition of mesmerism is an inhibition of a particular mode of activity of the cortex of the brain, in consequence of which the will can no longer be effective. This inhibition may be brought about by nervous impulses coming from certain sensory nerves, as those of sight, touch, and hearing. It may also be brought about by impulses or changes arising in the cortex itself. The inhibited cortex, and probably also inhibited lower centres of the brain, send out inhibitory impulses to all other parts of the central nervous system, so that the mesmerized male or female gradually passes into a state of torpor or even of complete anæsthesia. The phenomena of the excitable stage of mesmerism are proximately determined by the possibility of exciting any particular centre alone, without exciting at the same time other centres, by which its activity is normally controlled. In lower animals this stage is less marked, in consequence of a greater interdependence of the various parts of the central nervous system.

News of the Week.

M. Pasteur is going to Rio Janeiro to study yellow fever.

Our National Sanitary Patrol.—The Revenue Marine, consisting of 38 vessels and 950 officers and men, covers the entire coast of our country and acts when needed as a sanitary patrol.

Epidemic of Hydrophobia in Vienna.—A cable report, under date of November 26th, states that a veritable epidemic of hydrophobia is prevailing in Vienna. Already eighty cases have been reported.

Epidemic Dysentery.—The daily papers have had much to say regarding a fatal epidemic disease which has been attacking the inhabitants of Eastern Kentucky and Western Virginia. We are informed that the disease is a dysentery caused by drought, filth, and bad food. The stories regarding it have been much exaggerated.

A Hermaphrodite.—A person calling herself by the ambiguous name of Madame Duplex de Balzac, informs the profession that she (or he) has just arrived from Europe and "intends to exhibit herself (or himself) before any person who is anxious to enlighten himself on natural science." Dr. William T. Lusk certifies that Mrs. Duplex de Balzac is an example of hypospadias. The generation organs are those of a male, but the general habit of the individual (and it is this which makes the case an interesting one), is of the feminine type. The bones are small, the wrists and ankles are slender, the breasts, the hair, the complexion, and the voice are those of a female. Dr. William M. Polk states that it is a case of true hermaphroditism.

Money for Physicians' Widows.—The forty-second annual meeting of the Society for the Relief of Widows and Orphans of Medical Men, was held last week, and the following officers were elected by ballot: *President*—Dr. S. S. Purple; *Vice-Presidents*—Drs. J. L. Vandervoort, J. W. Warner, T. F. Coch; *Treasurer*—Dr. John H. Hinton; *Board of Managers*—Drs. G. M. Smith, T. C. Finnell, Afred C. Post, John J. Mulhan, Willard Parker, Isaac E. Taylor, and W. T. White. The report for the year ending September 12th, showed that the actual expenses of maintaining the Society were but $47.85, while the total receipts from various sources were $50,016.33. There was paid for annuities to 14 widows and 8 orphan children $4,252.50, and invested in bonds and mortgages $37,000. The total assets of the Society, on September 19th, were $143,447.96.

Suicide of an Insane Physician.—A Danish adventurer calling himself Dr. F. De Castro, committed suicide in Newark last week. His last will, dated February 12, 1883, read as follows: "After death I request that my body shall be given to the Chicago Medical College, or any medical college in the city of Chicago, upon the following conditions: After the body has been serving its medical purpose for science, the entire skeleton be placed in the museum with the following inscription on the brow of the skull: 'This is the skeleton of F. De Castro, the great traveller and linguist, who died a martyr for those he loved so well.' If the Chicago colleges will not accept the body, any medical college in the city of New York which will comply with my request may take charge of it."

The President's Message.—In his annual message, referring to the subject of cholera President Arthur states that, pursuant to his proclamation, the Secretary of the Treasury prohibited the importation of rags and the admission of baggage of immigrants and of travellers arriving from infected quarters. "Lest this course may have been without strict warrant of law, I approve the recommendation of the present Secretary, that Congress take action in the premises, and I also recommend the immediate adoption of such measures as will be likely to ward off the dreaded epidemic and to mitigate its severity in case it shall, unhappily, extend to our shores."

Regarding the Army Medical Museum, he says: "During the past session of Congress a bill to provide a suitable fireproof building for the Army Medical Museum and the library of the Surgeon-General's office received the approval of the Senate. A similar bill, reported favorably to the House of Representatives by one of its committees, is still pending before that body. It is hoped that during the coming session the measure may become a law, and that thereafter immediate steps may be taken to secure a place of safe deposit for these valuable collections, now in a state of insecurity."

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 11, 1884.

W. J. MORTON, M.D., PRESIDENT, IN THE CHAIR.

SPINAL CONCUSSION AND THE NATURE OF ITS SEQUELÆ.

DR. C. L. DANA read a paper on this subject (see p. 617).

DR. W. A. HAMMOND said: I agree with Dr. Dana in the view that there is such a thing as concussion of the spinal cord. I agree with him further in the doctrine that it is difficult for us to tell by the symptoms what the exact nature of the injury is that the patient has suffered. But this fact, I think, remains, that there is some injury which the spinal cord is capable of suffering, which is not of such a serious character as to cause death, and which is not accompanied by any injury to the bones, or to the muscles or ligaments. That after all is the practical point.

Dr. Hammond then related the history of two cases of spinal concussion in which he had been called as an expert. The first patient suffered from muscular weakness, spinal pains, severe general nervous symptoms, and walked with a peculiar paralytic gait. There was no positive evidence of organic disease of the spinal cord. He received large damages, but he still, twenty years later, suffers from his trouble. The second case, of a somewhat similar character, made a better recovery, but still walks with a cane. Dr. Hammond thought that this patient suffered from some organic disease of the cord.

The speaker referred to the first case which occurred in this country in which a post-mortem was made. The patient was a physician, who fell on the ice and suffered from the symptoms of antero-lateral sclerosis. On post-mortem, sclerotic patches were found throughout the spinal cord. I think traumatism may give rise to spinal affections without there being any palpable lesion of the soft parts, or of the bony structures, or the ligaments.

Only a few days ago I was called to the upper part of the city to see the case of a woman who had fallen through a dumb-waiter, a fire-escape, or something of that sort, which barely allowed her to pass in a doubled-up form. She fell a distance of thirty-five feet, by measurement, into the cellar, striking on her buttocks upon the hard ground. There was no fracture. Three months after the occurrence of the injury I saw her. She was still suffering from paraplegia and incontinence of urine, and paralysis. Hypochondriasis and hysteria had also developed to an extreme degree. Yet she is rapidly recovering. I do not think there was any hemorrhage in her case, because I do not think hemorrhages of the spinal cord are recovered from. She suffered not only from motor troubles, but from sensory disturbances likewise; also from atrophy of her limbs, showing that the injury involved the whole segment of the cord, both the sensory and motor parts. Yet she has recovered, and I do not believe, therefore, that in her case there was any destruction of the cord. I cannot conceive that there could have been anything else than a concussion.

Now, I would like to know what it is that happens sometimes when patients lift heavy weights and they feel something give way in the back, and after that they lose the use of their limbs, gradually waste away, and become paralyzed. I have seen such cases. I remember one which came under my observation some years ago, where the patient, endeavoring to lift a heavy window, got his hand in place and lifted with all his might, and suddenly felt something give way in his side. There was no injury there that could be detected by an examination; there was no fracture; no dislocation. And yet that patient gradually lost the use of his legs. What was that? Probably a rupture of some of the fibres of the cord or of the membranes of the cord; certainly an injury to the cord and not of the bony structures about it.

I cannot conceive of the possibility of getting rid of these facts, that the spinal cord is capable of suffering injury, without there being any detectable lesion of the soft parts, or of the bones, or of the ligaments, or intervertebral substance, and that the trouble inside of the spinal canal involves the spinal cord.

DR. CORNING related the history of a case in which partial impotency persisted long after the accident, and in which there were marked suicidal tendencies. There was not a trace of external injury.

DR. ROCKWELL considered that organic or structural conditions seldom followed concussion of the spinal cord. Notwithstanding the fact that at the present time he had under his care a young person who was suffering from typical myelitis, ascribed to a severe fall followed at once by incomplete paraplegia, which had gone on to complete paraplegia, it seemed almost incredible to him that a person could have severe concussion of the spine without the cerebro-spinal system in its entirety being involved. In concussion there seldom could be a rupture of the vessels or nerve-fibres without causing death. The majority of cases of concussion that had come under his observation had presented symptoms as manifold almost as those of neurasthenia. The prognosis was generally good, and the best remedy time. The concussion that follows the blow of a bullet was frequently observed during our war.

DR. HAMMOND added a case of railway injury, in which there was no lesion whatever of the external parts apparent; but there were ocular disturbances (which he thinks are rare, as Dr. Dana says). The patient had double vision; congestive disks; bird vision; and suffered from the symptoms of neuro-retinitis, but they eventually disappeared. He had marked paralysis of the nerve on one side. He was injured in the upper part of the cord; suffered from loss of power in his arms and legs. Had head symptoms, was hypochondriacal and hysterical. He recovered a very large sum from the railway company.

DR. WEBER remarked that from what he had seen and read upon the subject, it seemed to him that Page was certainly stealing a march upon Erichsen with regard to the views which Erichsen entertains. As I said in a paper read before this Society upon another subject, the more we shall get into the habit of including a thorough examination of the cord and its meninges in post-mortem, the more our knowledge upon the demonstrable lesions will increase, and the less we shall hear in the course of time of concussion of the spine. I do not mean to say that there is no such thing as concussion of the spine, but I believe that a good many cases which are considered as such are not (in spite of the symptoms pointing that way) dependent upon concussion of the spine, but upon concussion of the brain. Now, the case which has been related by Dr. Hammond, of the woman falling down a dumb-waiter, thirty-five feet, and striking upon her buttocks—taking it for granted that there was a complete absence of all injury to the soft parts and to the ligaments and bones, as Dr. Hammond stated—is a case more of concussion of the brain than of concussion of the spine.

DR. HAMMOND: To this I can only say, that there was no cerebral symptom—that was my understanding—in the early part of the disease.

DR. WEBER: There may have been, though.

DR. HAMMOND: I understand not. She never lost consciousness for a moment. I cannot conceive of concussion of the brain without loss of consciousness.

DR. WEBER: In an abstract of a large number of papers that I read recently, in a volume of Virchow-Hirsch's *Jahresbericht*, I found that most of the leading physicians abroad believe that many cases of so-called concussion of the spine, without any injury to the soft parts or the bones, really depend upon concussion of the brain. Some years ago I saw, at the St. Francis Hospital, a case precisely like the one related by Dr. Hammond. It concerned a young man who had been trying, on a wager with some other man, to lift heavier and heavier weights. While still straining he suddenly felt something give way in his back. He fell down and lost the use of his limbs. When I saw him, two weeks after the

accident, there was paraplegia of the lower limbs and a paralytic condition of his bladder. He remained in the hospital for some time, and failing to improve, he was at length discharged. I look upon this case as one of apoplexy of the spinal cord.

Dr. Roberts viewed the diversity of opinions as showing a manifest want of conception of fundamental ideas in regard to the subject. He considered the problem one of physics; dealing with a material object, and the forces acting upon it. Among the queries propounded occurs this one: Is it possible for the spinal cord to become concussed without injuring any of the hard parts of the vertebræ? Now, what is a traumatism? What is concussion? The effect of blows upon hard, and upon soft or elastic substances, is very different. And we have every reason for believing that this effect differs upon the hard and soft parts of the human body; for the effects considered from the physical standpoint are the same, so far as the mechanical effects are concerned. Vibratory impulses, we find, are conveyed with much greater facility along a hard wooden beam than they are through the atmosphere. Now, if we saw the beam in two and interpose an elastic buffer, it will be found that the sound will not be transmitted; a physical barrier to the transmission of these impulses has been interposed. I may summarize two or three principles which underlie this problem by stating that the harder the substance and the more direct its continuity the greater is its conductivity to jars, to vibratory impulses, to injuries. When a human being is thrown from a vehicle and strikes upon the ground, the force with which he is carried is represented by the rapidity with which the body is moving and its bulk. Now, it took a certain amount of force to set his body in motion, and it would take an equivalent amount of force to arrest that motion. When he strikes against the ground this motion is arrested; he must meet with a force equivalent to that which is represented by his momentum. The force is thus annihilated and is expended upon the jarring. How can these vibratory impulses affect the individual? We must examine the hard and soft parts, and the attitude of the individual, and from our examination of inert physical substances, we have reason to go at once to the bones for the channel through which these vibratory impulses can most readily be conveyed. The attitude of the patient at the time the blow is received is an important factor in determining the probable amount of injury. If the skeleton is erect and the patient is thrown forcibly upon his feet in the erect attitude, the resulting injury will be much greater than it would if he were in a crouched position. But then, in this stooping attitude, the limits of the elasticity of his muscles, and the limits of the elasticity of the flexure, may be exceeded when the blow is so severe as to overcome the power of the muscles to maintain this protective attitude. Another important factor to be considered is: whether the patient be fat or lean, for we are dealing with a physical problem. Elastic substances are always the materials with which we annihilate or absorb vibratory impulses. Strike a living skeleton, such as you see in our museums, forcibly upon the breast, and you produce a shock that may result disastrously; whereas a blow upon a well-developed pectoral muscle is received with impunity.

Dr. Græme Hammond did not think that there was any question at all that cases of congestion of the spine and symptoms referable to the cord alone did appear after the spine had been in receipt of an injury. He thought the question of the greatest importance was: What is the nature of the trouble with the spine? whether it is a morbid change which goes on progressively, or whether it is simply functional.

Dr. W. O. Moore stated that there were two classes of cases met with in ophthalmic practice. The first is that which me meet with merely upon the receipt of an injury to the spinal cord, viz., cases in which there was an increase in the circulation of the optic papillæ, and cases where there was decided neuro-retinitis. In one case there was atrophy of the optic nerve. Whether concussion took place as claimed by the history of the patient he could not decide, but two cases in his history book give decided evidence that concussion of the spine did occur. In one case the patient fell from the second story, striking mostly upon his feet and buttocks. His general health was at once affected, and he was not able to attend to business thereafter. He had more or less neurasthenic symptoms. Two years later failure of vision was noticed, from ordinary atrophy of the optic nerve. Color-blindness then appeared, first for red, then for green, then for yellow and blue, and then it was entirely gone. After ten years' failure of vision he is now totally blind, and has no symptoms of locomotor ataxia or anything of that sort. In the other case, the patient was thrown from his seat on a wagon and fell in a heap, without striking any particular part of the head. Atrophy of the optic nerve took place on one side. The case was under observation about two years, until finally the atrophy was complete and there was total blindness of that eye. In the other eye he did have for several days, two or three weeks after the injury, a flushing of the optic disk. At one time it was feared that it would likewise become atrophied. The last case was considered by some eye men rather a case of concussion of the optic nerve. That there is a connection between the symptoms of the spinal disease and the eye, there is no doubt. We see it causing atrophy of the pupil, and later on contraction of the pupil. He thinks there is no doubt a connection between the sympathetic and medullary fibres which go to the pupil. In these cases there was no direct blow to the eye nor head, and no laceration or contusion of any soft parts.

Dr. Dana considered Dr. Moore's cases extremely interesting, because they contradict entirely the very positive statements of Mr. Page in his work on "Injuries to the Spine." He then read the following letter from Dr. Allan McLane Hamilton regarding this subject:

"While I have been satisfied, from a very varied experience in court and elsewhere, that the vast majority of those who claim compensation for railway injuries are malingerers and impostors, I still find that nervous shock is quite apt to develop a 'railway hysteria' in some, which is in every sense a real disease, and is due to actual physical disease, and in others to the development of a morbid expectant attention. It is unnecessary to adopt the extreme opinion of either Erichsen or Page. There is in sixty per cent. of the cases an intermediate condition in which subjective symptoms are the only ones. In some of these cases the hemianæsthesia, lately described by Putnam, may be detected by abstract tests. In others we are furnished with vague yet unmistakable disorders of a functional yet serious nature. I strongly disprove of the injustice of juries who manifest an assinine disregard of scientific proof, and award enormous damages because of prejudice against corporations, simply upon the story of the plaintiff. On the other hand, there are cases turned out of court when some award *should* be made. I do believe that in the great number of well-established cases of railway hysteria, that *moderate* verdicts should be rendered, just as they are in punitive libel cases when the peace of mind has been hurt. In the majority of cases no speculative damages should be allowed upon a simple personal relation of symptom."

Dr. J. G. Johnson, of Brooklyn, asked Dr. Moore whether, in the case he mentioned, there was a connecting train of symptoms that showed that the blow did the injury.

Dr. Moore replied that the man who fell from the wagon was seen thirty-six hours after the injury. He had failure of vision from the very beginning; in that case he had flushing of the optic nerve, and decided symptoms of neuro-retinitis. This gave way after a period of two years, and atrophy developed. In the other case, where the patient fell from one story to the other, the patient

had double optic atrophy, which of course may have arisen from other causes. As far as I can get the evidence from Dublin, it was a decided case of concussion. As he remembered the case it began some years after the accident.

Dr. Johnson asked if there was an early history of the case?

Dr. Moore said there was not. It came on some years after this trouble. He had no evidence of locomotor ataxia.

Dr. Harwood remarked that, out of a number of sufferers from railway accidents, he recalled two cases of spinal concussion. He advised the patients and the corporation to settle amicably. But his advice was not taken in either of the two cases, and they finally went to trial. His view was sustained by the jury, and a verdict was secured for the plaintiff; but what is very unusual in these cases, as he had observed them in suits that had been brought, these patients ultimately died from the results of their injuries.

Dr. Adams observed that most of the cases that showed any injury after a concussion generally showed it in the lower extremities. Many cases of Pott's disease were recognized by most authorities to be caused by concussion. It would appear that the milder injuries caused ordinary concussion of the spine, and more severe ones Pott's disease.

Dr. J. G. Johnson: I only wish to say that a fact which would militate against any such hypothesis as that is, that in the case of vertebral caries, which, according to this theory, is supposed to result from more severe injuries, we have none of the symptoms of spinal concussion. I merely want to ask the neurologists one question, and that is, if they have ever seen a case of spinal concussion in a railway employee (who takes the risk of the conveyance) without the physical symptoms showing either meningitis or myelitis? These anomalous symptoms, which are laid down by Erichsen with such fluency of language, I have never seen in my twenty-five years' experience as a railroad surgeon. I have never seen a single railway employee have them. And for this reason: Dollars and cents do not enter into the consideration of the railway employee. He has every inducement to get well; he has his family to support; if he does not get well in a reasonable time he goes out, and somebody else takes his place. On the other hand, the man who has been on a railway train, who has a good shaking up and a terrific scare, has no object in getting well. The company has got to pay him roundly; it has to pay him for his loss of time; it has to pay him for his suffering, both mental and physical; it has to pay his surgeon also; his surgeon has an unknown quantity to handle; he has something to treat that the patient does not understand. If the patient has a broken leg he knows what he has got, and the doctor cannot come in and discuss spinal concussion symptoms, and all that. He has seen broken legs before; has had cold extremities, vomiting, exhaustion, and so on; but he has not had the scare of a doctor coming in, feeling up and down his back to see whether it pains him, and asking him whether he can stand on his legs, and going through all those symptoms, that unknown quantity which they know so well to do. He has not had some confrère to come in and suggest some more doubts. The doctor, in a good many cases, is hungry, and the big corporation may pay his bill. He has to examine that back often; he has to find out just what these doubtful things mean; and the patient, having it iterated, and reiterated, and reiterated again, begins to believe himself that there is something terrible the matter with him. He does not dare to go out and take a little fresh air and exercise (which, as my friend, Dr. Hammond, says, is the best thing to restore the nerves), because a railway man might be around and spy him using his limbs. He gets morose, and has no object to get well, because that suit is not settled. He begins to have some motor disturbances; he has these profuse sweats, etc. When you come to take that kind of disturbance—of expecting to recover from the company—out of the question, they get well very frequently with indecent haste.

In regard to the claim of destruction of the virile power, which has been alluded to here by one of the speakers this evening, that is one of the most common allegations that have been made in these cases. I reviewed that point in a paper on "Railroad Injuries," read before the Medico-Legal Society.

I think there is no doubt that serious lesions of the spine and spinal cord do occur as the result of railway concussions. We have also mingled with it a large variety of other symptoms. When a train is suddenly stopped, the patient is violently thrown backward and forward, shaking up all the viscera, and the whole sympathetic nervous system, and the other organs suffer. Added to that this terrific fright and the utter helplessness of their condition and the effect upon the mind is something which is severe. But with all that, when you come to consider the fact of compensation, we find these cases so much aggravated that I do not think any physician is right to go into court and swear that the patient has disease of the spine unless he has the physical symptoms, and he should not simply relv upon the statement of the patient, who is interested to make matters as bad as he can.

I saw an extremely interesting case some years ago, which was the result of a railroad disaster on the New York Central Railroad. The patient, a lawyer in this city, was in a sleeping-car when it was derailed. He was thrown down an embankment, and I saw him the next day but one. He was in such a condition that he was put on a return train and came to Brooklyn. There were marked contusions of his shoulders, abdomen, breast, back, and hips, showing that he had received a violent rolling over. Some thirty-six hours from the time of his injury his limbs began to fail him. He could walk if he was watching where he placed his foot. If he walked, and you would speak to him, he would tumble over. That increased, and paralysis of sensation followed, until it extended up as far as the ninth dorsal vertebra. There was no shamming about it. I tried electricity; I burned his legs with matches, and things of that kind, which he would not have been able to stand if it had been felt. Dr. Ranney saw the patient on behalf of the New York Central Railroad Company. The case was settled at about twenty thousand dollars. Dr. Ranney based his claim that he would recover on the fact of there being no wasting of the limbs. I at that time held the opinion that it was an extravasation of the blood around the substance of the cord; I did not think it could be in the pith, from the fact of its being limited to the nerves of sensation and not of motion. After that he recovered entirely and thoroughly, and his own physician and myself, who examined him subsequently, failed to find any indication of any physical pain whatever. He recovered in about six months.

There is a point of interest in regard to these spinal cases alluded to by Erb, that I would like to hear about from the neurologists. Men long connected with railway trains, as engineers, after a while lose their snap; they don't get in on time. Finally they show a complete nervous break-down. Erb alluded to this particularly. What change has probably taken place in the old railway employees where there is this nervous break-down, which shows itself by a lack of courage and nerve-power, and by gradual failure? These cases are becoming extremely interesting in Germany, where the railway employees are allowed damages, just the same as passengers on trains, and this old, worn-out railway nervous system is being put in as a spinal concussion.

Dr. Birdsall thought that these cases were a good deal rarer than the general impression would lead one to conclude. The prominence which the work of Erichsen had been given, had led people to look for effects of spinal concussion, and to talk about them a good deal

more than was really admissible from the facts of observation.

He had been led to conclude that many patients had, previous to their concussion, what was ordinarily termed neurotic or neuropathic constitution.

It had been stated by Dr. Weber that many of these symptoms were cerebral. He thought they were developed, probably, as much from fright as from concussion of the spinal cord. On the other hand, he would not be understood as denying the existence of functional, and perhaps something more than mere functional, disturbances of the cord from concussion. There was a good deal of difference between a single shock, a severe shock due to railroad accident, and the continual jarring which went on in a man in the cab of an engine. It seemed to him that in a healthy person, while the former might be readily recovered from, the latter, even of a more moderate character, would prove more injurious, and he should certainly be very careful about classing them in the same group.

Dr. Johnson said the length of time, doubt, and uncertainty of the cases are important elements to consider. As far as a surgeon for a railroad company being affected in his evidence by outside influences is concerned, he would find that truth was the first essential; he would not hold his appointment for twenty-four hours when his company was satisfied that he was not truthful. When we are sent to investigate a case on behalf of the corporation, we make as thorough and as exhaustive an examination as it is possible with the knowledge that we have, and our report is made in writing and goes to the company's office, with everything bearing against us as well as bearing for us. If we misrepresented that case, and this is shown in evidence in court when the case comes to trial, it shows that we are ignorant or dishonest, and our walking tickets are prepared. No man can hold his position as a surgeon for a company who is not honest, because they pay by dollars and cents on an opinion, and if it is not truthful they do not want it.

Luther R. Marsh, Esq., said he was bewildered by the medical phraseology, which transcended that of the legal guild in the magnitude of its technology. If he were to ask the doctors the difference between "the whole of an undivided moiety, and the moiety of an undivided whole" they would understand his meaning, but they could hardly use a neurological sentence that would not send him to his dictionary. When quite a young man he had written an article for a local newspaper, without regard to sense, but simply for the cadence of the sentences. The beginning of that article, which the good people of the town puzzled over with their glasses, ran as follows: "Pedaneous are the gorgeous geoponics of saginated hoplites." But while his big words were without meaning, theirs were not. He had gleaned from them that the spinal cord was certainly capable of injury, without any necessary harm to its bony or other coverings. The paper had seemed to him eminently impartial, steering a midway course between what the transportation companies might call the extravagances of Erichsen, and what suitors for personal injuries might class as the perversions of Page. He had also learned that when a man had been concussed, as the doctors called it, in the nerve-centres, he was never thereafter fully himself again. He did not, however, consider the word "concussed" felicitous. He was pleased to learn from Dr. Roberts that it was a good thing to be fat, and have a shield between one's self and harm. He considered this well shown in Dr. Hammond's case, where the woman was saved by landing on the voluminous natural cushion of her seating apparatus. The insinuation which had been made, that the consideration of the fee could swerve the testimony of the physician, he repudiated, and said that he stood up for the honor of that sacred calling which deals with the mysteries of human life, and which he had always held in reverential regard. From Dr. Dana's paper he had seen that he agreed with Charles Sumner, that what a man most needed was backbone; that wonderful combination which enabled a man to stand erect, and firm, and unbending, in all emergencies.

Dr. Dana: I only wish to say with regard to one or two points that Dr. Johnson raised, first, with regard to employees not suffering from this concussion of the spine; I think he will find the symptoms of concussion of the spine, as delineated by Dr. Erichsen, were described by Dr. Abercrombie twenty-five years before Erichsen wrote, and his classification of spinal injuries would hold good now.

He was very glad that Dr. Johnson brought out the great importance of the malingering element, because it is an important one. Every one knows there is a prejudice in juries against corporations. There are certain courts where a corporation cannot get a verdict any way, at least so the lawyers say. Therefore, I think that in justice we ought to keep that fact of malingering before us as being a very important one indeed.

As regards the trouble brought on in locomotive engineers, he thought that Dr. Johnson would find that Dr. Rigler, whom he quoted in his work on "Injuries of the Spinal Cord," has devoted a good deal of attention to this disease, which he calls sideromorphophobia, or fear of railways. He did not think that it was due to continuous concussion alone, because it occurred in locomotive engineers more often than in the other employees. It seemed to the speaker that the constant strain and anxiety which these engineers suffered were very important elements in producing it.

In conclusion, he said that there was a class of cases that had not been much referred to in the discussion. Nervous and hysterical women, when frightened or injured on a railroad, were very liable to go to bed, and, under the sympathizing influence of friends and the prospect of large damages, develop a functional paraplegia with symptoms of spinal irritation. It was often hard to tell the exact amount of real injury for which the company was responsible. As a rule the companies were unjustly mulcted, though sometimes the trouble became a real one.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY.

Stated Meeting, November 26, 1884.

E. C. Harwood, M.D., President, in the Chair.

LEAD-POISONING.

Dr. R. C. M. Page read a paper on the above subject (see p. 621), the discussion on which was as follows:

Dr. Flint: In a meeting of this kind it is more pleasant for me to listen to others than to occupy time by my own speaking, but I will with pleasure make a few remarks on the paper. In the first place, as to the name: it seems to me to be a misnomer to call it colic at all, as the colon is not specially involved. It has nothing to do with a spasmodic affection. I consider that it is a neuralgic affection. One curious fact in connection with it is the different way in which it manifests itself in different persons as regards their susceptibility. Out of any given number of persons who are exposed to it, a certain number only are affected by it. I cannot explain this, and do not know that any one has ever been able to do so. Another curious fact in connection with it is its limitation to the extensor muscles. I do not know that that has ever been satisfactorily explained. In many cases the flexors remain unaffected. I think Dr. Page will recollect a hospital case, many years ago, which well illustrated that fact. It was before the elevators had been introduced, and as it was necessary to take the patients from the lower wards up to the amphitheatre, it was sometimes a puzzle as to the manner in which we could do this. I had a patient who had the drop-wrist to a remarkable degree, and he had no power over the exten-

sors. We wanted to take another patient up-stairs, and we took this patient, who was a very muscular man, and raised his hands and gave him a good grasp, which was necessary. Having done this, he took hold of the patient and carried him up three or four flights of stairs easily enough. That case illustrated to a remarkable degree, I think, the fact that the paralysis was limited to the extensors, and that the flexors were exempt. We find sometimes the same paralytic effect on the toes, as connected with their extensor muscles. I can hardly agree with the writer of this paper as to the importance of the diagnosis of the blue line. I cannot cite statistics, but I am accustomed to find it more often than in the data which he has mentioned. It seems to me that in a large number of cases we can distinguish the blue line readily from the discoloration mentioned, and it is often a very useful point in diagnosis. I have been led to think that we neglect the examination of the urine too much. I was led to think so by a case which I saw several years ago with the late Dr. Stoner of this city. It was a case in a child, seven years of age, who had complete paralysis of the flexor muscles of the forearm. I told Dr. Stoner that it was a case of lead-poisoning. He said: "It looks like it, it is true, but it cannot be, for the reason that it is impossible. This child has not been exposed to the causes which produce lead-poisoning. There is no possibility of the child having been exposed to lead." The child at that time did not show the blue line. It occurred to me to have the urine examined. We did so, and sent a specimen of it to Dr. Doremus, and the examination showed conclusively the presence of lead. My impression is that it is now a common practice to examine the urine. It is not a difficult one, surely. The question that arose after we had found out this much was, How did this lead get into the child? After a great deal of inquiry the facts in the case seemed to be these: The child had been accustomed to play with leaden soldiers, and it was recollected that he was accustomed to have them in his mouth. With respect to treatment, I am very glad to be able to concur with the writer of this paper. It seems to be a fact that the treatment formerly consisted of the stereotyped drastic remedies. The writers of some years ago followed a course of treatment that consisted in the administration of cathartics. The French writers on the practice of medicine seem to observe that method of treatment. I think it is also followed by the English practitioners more than by us. I cannot think that it is a rational method. It is injurious to a greater or less extent. I believe the plan that has been indicated in the paper is to relieve the pain by opium, and pay no attention to the bowels, except so far as the moral effect is concerned, or to obviate too prolonged a siege of constipation, and then to eliminate the lead from the system by the iodide of potassium. I cannot, however, but be somewhat skeptical as to its efficiency. I have given it in a great many cases without any good effect apparently, and have been ready to think sometimes that we overestimated its value. In a large number of cases where the iodide of potassium has not been used, they have ended about as well as if it had been used. I simply throw out that idea, however, and do not give it as an opinion.

Dr. Little: In what way is the lead rendered volatile by turpentine? I believe that Dr. Page in his paper said that the use of so much turpentine rendered the paint volatile, and consequently led to its inhalation by the painter. I did not know that any of the paint that was commonly used was volatile enough to be thrown off with the turpentine and inhaled by the patient. It has often occurred to me that lead-poisoning is produced by the use of lead as an astringent. I have never yet seen a case, however, in which lead-poisoning was produced by the use of lead in this connection. Maybe its use, however, is not continued long enough. I have never seen any bad effects from the use of the iodide of potassium.

Dr. Blumenthal: I think Dr. Page has pretty thoroughly covered the whole field. The recognized treatment certainly is that which he has just outlined. It consists, in the first instance, in the relief of pain by an opiate treatment in conjunction or not, as the case may seem to demand, with croton oil, and after that the elimination of the lead from the system by the iodide of potassium. If I am not very much mistaken there often remains a good deal of atrophy after all traces of lead have been eliminated from the system. I have often got a great deal of encouragement by the use of nux vomica and strychnine while using electricity. The tonic treatment that has been pointed out is certainly one in which we all agree. There is a vast amount of difference in the systems that absorb the poisons—that is, some will absorb more poison than others before they present symptoms—and consequently there must be a great deal of difference in the treatment that may be necessary to produce relief. The most probable reason, to my mind, why the right hand is affected oftener than the left is that it is used more by the workman than the other. His right hand is very frequently covered by the paint, and consequently there is more opportunity given for the absorption of the lead than in the case of the left hand. Before the patient feels the effect on his system his limb is likely to be affected. Of course where he is left-handed the reverse would be the case. The point which Dr. Flint raised is a very important one, and that is that we are too likely to look after other symptoms and not pay enough attention to the urine.

Dr. Baruch: I have used very frequently an application of white paint to burns, just as the painters do, quite as thick as I could use it—just thick enough so that I could handle it properly. I employ it in connection with about two per cent. of carbolic acid. I have used this in connection with dilute sulphuric acid lemonade, and I would like to have the question settled here whether there is any necessity of giving a patient this sulphuric acid lemonade while he is being treated with applications of white paint.

Dr. Wood: One idea has struck me in Dr. Baruch's address, and that is whether we do not run a great risk, when we use white paint for several days over a large surface, of producing lead-poisoning; and yet I must say that I have never come across such a case. I have, however, seen the symptoms of lead-poisoning from the use of lead internally. I once saw a case that was called chronic diarrhœa in one of our soldiers of the late war. He had been taking the acetate of lead, and when he came North he continued it for some time; how long I am not able to say. When he returned he had symptoms of lead-poisoning. I believe it is generally conceded that the drastic purgative treatment of this disease is not carried out to the extent that is recommended in foreign works. There is no question but what the soothing opium treatment conduces more to the recovery and convalescence of the patient than a cathartic treatment.

Dr. Dessau: I was quite surprised to hear the writer of the paper speak so disparagingly of the treatment which consisted of the use of alum and sulphate of magnesia. I have used hypodermic injections of morphine to relieve pain also, but the constipation was relieved by the use of sulphate of magnesia and alum, and it was used in very large doses. I used about a drachm of the sulphate of magnesia every three hours. Soon afterward the bowels were relieved. After this the patient is put upon the iodide of potassium treatment, but the constipation in my case was certainly relieved by the use of alum and the sulphate of magnesia, because no other treatment was resorted to. This particular patient had been constipated for a week.

Dr. Fuller: I cannot say anything with regard to the treatment of the case, but the other day I had the opportunity of observing the disease in children of very tender years. The author of the paper did not mention particularly the occurrence of the affection in children,

but only spoke of adults. The cases I saw were the youngest I had ever taken notice of—they were only three or four years of age; they were undoubted cases of lead-poisoning. The history of each case could be traced exactly: Their father was a painter, and the closet in his house contained paint; they contracted the disease from this. They had a great many forms of treatment applied to them without any appreciable results. They were affected both in the upper and lower extremities.

Dr. Leonard: I saw an unusual case while in the Adirondacks, which was diagnosed as lead-poisoning. After the case had existed for some months it was cured by the use of the iodide of potassium treatment. The patient was a hunter who had tried to stop chewing tobacco, and to accomplish this he had put a bullet into his mouth, and the disease was attributed to this cause.

Dr. Little: I would like to ask concerning the use of sulphuric acid as a prophylactic. Dr. Baruch has said that it should be used as a lemonade. I have not had any experience, but I have noticed that it has been recommended by the authorities.

Dr. Flint: There has been one topic which has not been referred to, and that is the relation of lead-poisoning to gout. It has been asserted that gout has followed where lead has been introduced into the system. I would like to ask those present if they have ever known of a case where they could attribute gout to lead-poisoning.

Dr. Chamberlain: Something has been said about hair-washes as productive of lead-poisoning. I recollect a case twenty-five years ago where the disease was produced by this influence. I think it was published in Wood's *New Remedies*. All of the preparations mentioned contained lead, and evidence was brought forth to show that lead-poisoning was produced by the use of these preparations.

Dr. Fruitnight: It has been emphatically stated that other muscles besides the extensors are affected. Last summer a patient presented himself at my office. He worked in Western Pennsylvania. I asked him to strip himself, and on removing his clothing I observed that the muscles of the upper extremities were all more or less atrophied. He had to be assisted in taking off his clothing. He had worked a year in the establishment in which he was at that time employed. I endeavored to find out every possible cause for his condition, but was forced to the conclusion that lead was the cause. I questioned him with regard to other men working in the same establishment, and he told me that a great many of them had suffered from the drop-wrist. Another patient was a printer who had been a very adept workman, but at last he became unable to fulfil his duties any longer as readily as he could before. His muscles became weak, and he had pains and was beginning to waste away. I saw him about two months afterward and noticed that there was no reaction to the electric current either faradic or galvanic. I kept him under the usual remedies for about six months without any effect.

Dr. Page, in closing, said: I have very few remarks to make. In regard to Dr. Flint's cases, where the iodide of potassium failed, it is very likely that the patients did not take it regularly and continued to be exposed to the infection of the poison. In that case they were hardly fair tests. With respect to the blue line, I have nothing more to add. With regard to the remarks of Dr. Little on the volatilizing of the paints by turpentine, I would say that I do not know that such is the case, but believe it to be so. With regard to Dr. Blumenthal's remarks concerning nux vomica, I would say that of course it may be given. I thought that I had included it in my remarks on the general treatment. With regard to the remarks of Drs. Baruch and Wood about painting burns with paint, I do not think that any burn will last long enough to cause the patient to be poisoned with applications of lead, but if it does, I do not think the sulphuric acid will prevent it. I have known painters to take it regularly three times a day and yet be the worst poisoned men of the lot. In reply to Dr. Dessau, I believe that the morphine cured the patient. My point in regard to Epsom salts and alum was that the theory of sulphuric acid acting on the lead in the system is of no value. Concerning Dr. Fuller's remarks about children, I must say that I never came in contact with children that had lead-poisoning, but that all my cases were adults. Drs. Chamberlain and Harwood spoke of hair-washes as a cause of lead-poisoning. I would say that they are said to be a frequent source of lead-poisoning with ladies. There is no way to stop it that I know of except for the ladies not to use them. You cannot make people stop manufacturing them. Consequently if ladies will use cosmetic slops and greases they must expect to suffer the consequences. With regard to what Dr. Fruitnight has said about the flexors, there is no doubt in my mind but what the flexors become affected in time. The reason I think why it does not become more marked in the flexors is because the patient stops work in time. He is not exposed to the poison any longer and is undergoing treatment. I know of no case of gout traceable to lead-poisoning.

Dr. Wylie read a paper (see p. 624) on "Vomiting in Pregnancy," the discussion on which was as follows:

Dr. Baruch had seen one death, in consultation, resulting from vomiting in pregnancy. He had, however, seen death imminent in three different cases of pregnancy, in which he had been forced to produce abortion. He had noticed at that time, after introducing a bougie into the uterus overnight, and allowing the remainder to coil up in the vagina, that there was no vomiting. On such occasions there would be no vomiting, and labor would not come on for two or three days. Two or three hours after the bougie was introduced the vomiting would cease. He attributed this to the fact that the connection between the fœtus and the uterus was disturbed. This dilatation of the cervix was a dangerous precedent, and should be resorted to only in desperate cases. He had used it in one case successfully! When producing abortion he would first dilate the cervix before going on. The pathology was not at all clear. He had two cases of sterility. In both he had succeeded in curing the sterility by dilatation. In one of these cases he had a very bad case of vomiting, in fact as bad as he had ever seen not to be dangerous.

Dr. Powell would like to add one case in support of Dr. Wylie's view. It happened three of four years ago. He met Dr. Wylie on the street, and told him that he had been called in to see a woman suffering from vomiting, and gave the history of this case. It was the fourth pregnancy, and she had never reached full term, and premature labor had to be brought on every time to save her life. At Dr Wylie's suggestion the cervix was dilated at once. Dr. Powell went by no especial rule, simply dilating it until the woman said that it pained her a little. His finger passed in for about half an inch. The result was marvellous. She went to sleep within half an hour afterward, and never had the least trouble with her stomach. She has been pregnant and delivered at full term a second time since.

Dr. Fruitnight said that his brother, the late Dr. William Fruitnight, had a case in which the obstinate vomiting was overcome by means of dilatation of the cervix.

Dr. B. F. Dawson had no experience in it. He had not dilated a cervix in five years, except for the purpose of curetting the uterus. He would like to ask Dr. Wylie how one dilatation will correct disease of the cervix. It seemed to him a dangerous proceeding.

Dr. Wylie did not claim that it necessarily cured the disease, but that it took off the tension and served to relieve any hardening that prevented the tissues from swelling. Dilatation counteracts the disease. He had some doubts, the same as Dr. Dawson, years ago, when he first tried dilatation. These had been dispelled, however, and six weeks ago he was bold enough to dilate here, in his of-

fice, the wife of one of the ministers from Washington, and relieved her vomiting almost at once, which had resisted much dosing by the mouth.

Dr. Dawson thought that cases had been heard from where vomiting occurred simultaneously with pregnancy, and continued right along through it. We all know the effects of warm water, glycerine, and iodoform, and as Dr. Wylie uses these in making his applications, may not they be the means of giving relief?

Dr. Wylie: Hardly; for Dr. Copeman and many others cured by dilatation, pure and simple. As a rule, if you examine women that are pregnant you will find that they have a healthy cervix when they have no vomiting, and when they have vomiting you will find that they have a contracted or an indurated cervix.

Dr. Little said that a friend of his had tried dilatation and found it very good.

Dr. Dawson asked what was the psychological effect that was produced by this act?

Dr. Wylie could not say.

Dr. Copeman: In dilating, intending to induce abortion, there was an accidental delay, and he found that nausea stopped. It happened in a second case, and then he believed that dilatation had prevented it. Quite a number have followed him since then, and established the fact that it can be done safely and satisfactorily.

Dr. A. S. Hunter had no experience with the dilatation of the cervix, but he was very glad of the opportunity of listening to Dr. Wylie's paper, for it encouraged him in the use of that means in the event of the failure of medication. He had lost one case in his professional career from severe vomiting alone. The patient was forty-three years of age, and had vomited a great deal. If labor had been induced she would have died without any loss of blood. He had been successful in many cases by the use of oxalate of cerium and ingurim; five-grain doses of each. It has given prompt relief. He once knew of a woman who the morning after marriage was seized with vomiting, which continued for three months. When delivery came on it was evident that conception had occurred at that time. The patient that he lost died just before he read the paper of Dr. Copeman, and he was very sorry that he had not known of it in time.

Dr. Harrison agreed in most of the conclusions of Dr. Wylie. His only objection to his etiology was that it was not quite comprehensive enough. He had seen one case of obstinate vomiting. He included every case of vomiting, as, for example, any disease of the kidneys or disease of the stomach, and he came to the conclusion that there must be some local cause, and in the case he had in mind he thought he would have to produce an abortion, as the patient was so very much exhausted. Dr. Thomas was added to the list of consulting physicians, and he insisted upon it, said that it was absolutely necessary to induce an abortion, which he did with the effect of curing the patient. In this case the cause of the vomiting was due to peritoneal irritation from previous peritonitis. The uterus was bound down by false adhesions, and afterward she became pregnant. He thought it was the peritoneal irritation produced by the expanding uterus that caused the vomiting. In another case of severe vomiting the patient had taken some pills to bring on an abortion. It produced gastro-intestinal catarrh, and subsequently she had an attack of acute atrophy of the liver, which caused her death. He never saw a worse case of vomiting than that.

Dr. Dawson asked how Dr. Wylie would explain the fact that most women stop vomiting after a few weeks without dilatation.

Dr. Wylie: After a few weeks the cervix may soften to such an extent that the pathological condition which may have existed has been really changed by the softening process which takes place. My experience has been that the dilatation does not necessarily remove the abnormal pathological conditions of the cervix, but relieves the tension that seems to be the cause of the vomiting. That is, according to the experience that I have had.

Dr. Dessau had a case once where a woman called in to see him on account of persistent vomiting. She was then about in the commencement of the ninth month of pregnancy, and she told him that the vomiting had not commenced until about the month before. About four or five years ago a case happened where vomiting terminated with the birth of the child. Here the vomiting came on at the end of pregnancy.

Dr. Wylie said that pregnant women might contract diseases that might affect the cervix, such as venereal disease. He had known of one or two cases where the irritation of the vulva from venereal warts seemed to cause the vomiting.

Dr. Jacobus: In a case at his clinic one of the patients had lacerated her cervix, which had been treated by amputation with galvanic cautery. She did not want to become pregnant, and said that if she did become so she would in all probability miscarry. Later she became pregnant, and was quite put out about it, and was somewhat disposed to blame the treatment for getting her in that condition. It amused her husband considerably. She had practically no cervix, only an internal os. If dilatation would be likely to do harm I should think it would have done so in this instance. Dr. Wylie ought to recollect her, for he sent her to him. She did not succeed in producing miscarriage, and Dr. Wylie dilated her os, and the next day she had some symptoms of miscarriage. After the dilatation she walked home and took aloes pills, and had a flow. Then the husband came around and said that the flowing had ceased. Dr. J. sent back by him some morphine pills. About a month afterward she came around for some pills, and I found that she was still pregnant. She went on, and in about seven or eight months had a child. If dilatation was dangerous and produced miscarriage, it should have done so in that case. He thought that she would have gone the full time if she had had a cervix. She had a flow of water there for two weeks on account of a rupture, yet she was delivered of a child which lived.

Dr. McLaurey had seen some very severe cases, but never a fatal one. The most successful remedy that he could use was morphine and bismuth and caffeine. He had found that to be a very excellent remedy. He had never tried dilatation. In speaking of psychological influences he would like to state this. Occasionally he found a lady complaining that as soon as she becomes pregnant her husband becomes sick. A few weeks ago a lady came to him and said she was pregnant. I said to her: "How do you know you are?" She said, "Oh, as soon as I am pregnant my husband always becomes sick. This is the third pregnancy I have had, and my husband is sick every day." He had heard of this fact before, but he could not explain it, and would like to know if there was any one in this room that could.

Dr. Chamberlain was familiar with the paper of Dr. Copeman, and had employed his methods with satisfaction. He would remind the gentlemen of Dr. Engleman's paper that was published. He was inclined to regard the interpretation of this nausea as a neurotic phenomenon. The cervix is the most important portion of the uterus. Up to the time of birth the cervix is in volume as great as all the rest of the uterus, and up to the time of puberty there is a portion of the uterus that is between the reflection of the peritoneum on the bladder and on the rectum and the vault of the vagina; a portion between those is of the same volume as the uterus. The lower portion of the uterus is thrown down, and the upper portion is thrown off. The cervix is the active portion of the uterus. It is through that portion that the nerve supply reaches the uterus, and it has been observed that the neurosies (?) of the uterus are connected with the cervical portion. He had dilated the uterus repeatedly where he had attempted to bring on delivery in cases of convulsions, and as often as he had done that

thing he had found that the convulsions had ceased. Repeatedly, and he thought constantly, in every case where he had employed this dilatation of the cervix to suppress vomiting in pregnancy, it had been successful. He recollected a case in which a lady had a small fibroma on the posterior wall of the cervix. It acted like a kind of a ball-valve over the os internum. In that case he dilated the cervix and the vomiting stopped and did not return. He was convinced from experience that while undoubtedly such cases as Dr. Harrison has cited, where there is a palpable structural change, and this may become the cause of vomiting, and also in Dr. Wylie's cases, where he describes disease of mucous membrane, the treatment should be that of the mucous membrane. He was confident, nevertheless, that the kind of spasm which was remedied by the process of dilatation was the cause of a great many cases of severe vomiting in pregnancy.

Dr. Wylie had nothing to say, but admitted the paper was not as broad as it might be, as Dr. Harrison said, and it was drawn strongly in one direction so as to bring this point out: that local treatment can be given without great risk, and is in most cases the best, and in some the only, means of giving relief.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PULMONARY SURGERY—A NEW UNIVERSITY FOR LONDON—SMALL-POX AND CHOLERA—SURGICAL SCARLET FEVER.

London, November 15, 1884.

At the last meeting of the Medico-Chirurgical Society a brief but interesting discussion took place on pulmonary surgery. Dr. Cayley showed a specimen of cancer of the œsophagus associated with a pulmonary cavity. The cavity was tapped during life by means of a trocar and canula. It was found at post-mortem that the pulmonary cavity was in communication with the cancerous tract in the œsophagus and stomach, and that the fluids from the diseased area passed into the cavity. The case was obviously one in which a cure could not be expected; but the operation afforded the patient great relief by obviating the fetid expectoration from which he had been suffering. The case also shows that the lung can be tapped without much danger. In this case several punctures were made, without success, in various directions before the cavity was reached, and the patient had not suffered therefrom.

A proposition is on the carpet to found a new university for London. London's present university occupies the anomalous position of being merely an "examining board," though in this respect it performs its functions so hypercritically as to rather deserve the name *dura*—than *alma*—*mater*. It also stands in an isolated position without any very direct relation with medical and other colleges, and with practically no control over the teaching its alumni receive before presenting themselves to receive its official stamp. It is now proposed to found a new organization, with several faculties, with complete university teaching, supervised by the university authorities, and to bring it into close relation with existing institutions. An attempt will be made to merge the present in the new university. Active support is already promised from influential quarters. The Council of Legal Education will, it is believed, support the scheme. Earnest support may be expected from the medical schools and corporations. The Normal School of Science at South Kensington may also not improbably throw in its fortunes with the new scheme.

There is reason to fear an increase in the small pox epidemic as the winter comes on. The number of cases under treatment in the hospitals, etc., of the Metropolitan Asylums Board has again increased. The number of new cases admitted last week was more than double that of those admitted the previous week, viz., two hundred and thirty-three, as compared with one hundred and one.

The outbreak of cholera in Paris suggests the possibility of one here; but we can as yet show a clean bill of health.

At the last meeting of the Medical Society of London an interesting paper was read by Dr. De Haviland Hall on the subject of "Surgical Scarlet Fever," and was followed by a lively discussion. Several speakers doubted whether such cases were really scarlet fever, and it was suggested that the eruption might be really a rash due either to the shock of the operation or resulting from the anæsthetic used. No speaker ventured to defend the view that the performance of a surgical operation can originate such a disease as scarlet fever. Dr. Hall thought the poison had been absorbed before the operation, but that it would not have manifested itself so soon (in this case on the day following the operation) unless, as Sir J. Paget says, the health had been disturbed. Sir J. Fayrer, Mr. R. W. Parker, and Mr. Durham all regarded the case as one of scarlet fever. Mr. Parker remarked that his experience at a children's hospital had taught him that the occurrence was by no means rare in surgical cases which had recent wounds, and the scarlet fever might be very severe and the wound take on fresh action.

ON LARGE DOSES OF THE POTASSIUM IODIDE IN THE TREATMENT OF THE LATE LESIONS OF SYPHILIS.

To the Editor of The Medical Record.

Sir: In The Record of the 22d ult., p. 584, Dr. J. S. Crawcour, M.R.C.S. Eng., refers to an editorial on Dr. Seguin's article in the *Archives of Medicine*, on what is claimed to be the American mode of using the iodide of potassium in the late lesions of syphilis. In this article Dr. Seguin is quoted as claiming that the practice of giving very large doses of potassium iodide in certain cases has been in vogue for over fifteen years. "By large doses is meant such as make up a total of two and a half to ten grammes in twenty-four hours." Dr. Seguin is shown to have claimed that this practice originated with the late Dr. Wm. H. Van Buren, about fifteen years since, and that "it has received slight or no adequate notice in text-books," and that "it is only in the works of Loomis, Bartholow, and of Van Buren and Keyes, and Bumstead and Taylor, and of Buzzard, abroad, that any recognition of it is found."

Dr. Crawcour objects to the claim made by Dr. Seguin, that the administration of large doses of potassium iodide in the late lesions of syphilis originated with the late Dr. Van Buren, and thus was of American origin, and quotes a prescription made by himself in 1859, which calls for one drachm of the potassium iodide to be given four times in the twenty-four hours. He says: "It will thus be seen that the method of giving the iodide of potassium in large doses is by no means a New York method, but was used in New Orleans twenty-five years ago, and as," he says, "I had only been in this country five years, it might be more correctly termed an English method." It appears to me that Dr. Crawcour is quite justified in assuming this as far as any statements made by Dr. Seguin are concerned. Dr. Seguin was in error not only in attributing to Dr. Van Buren the credit of originating the plan of treatment of late syphilis by the iodide of potassium in large doses, but in his statements as to the comparative ignorance of the profession at large in regard to it, and also that "it is only in the works of Loomis, Bartholow, and Van Buren and Keyes, Bumstead and Taylor in this country, and of Buzzard abroad, that any recognition of it is found." According to the definition previously given of *large doses*, anything above two and a

half grammes, *i.e.*, about forty grains, may be considered as coming within the meaning of the term.

Ricord, in 1835, says of the treatment of the late lesions of syphilis by large doses of the iodide of potassium: "Two scruples may be given at first, in three doses, in the course of a day; fifteen grains should be added every five days until one and a half drachm (about five grammes) are taken a day, which I have rarely gone beyond." This passage occurs in the work of Hunter and Ricord (on Venereal), of 1835, and may be found in an American edition of the same edited by Dr. Bumstead, in 1853, p. 470. Acton, of London (1860), quotes the above with approval. Lancereaux, of Paris (Sydenham edition, p. 320), says: "The doses in which iodide of potassium is given vary from seven and a half and fifteen grains to forty-five, sixty, seventy-five, and ninety grains in twenty-four hours. Some practitioners carry the dose to *one hundred and fifty, one hundred and eighty, and two hundred and twenty-five grains or even more.*" Beaumler on syphilis, in "Ziemssen's Cyclopædia," vol. iii., p. 297, says of the use of iodide of potassium in the treatment of late syphilitic lesions, "even thirty or forty-five grains several times a day must be given to attain a cure."

Mr. Coulson in his treatise on "Syphilis" (London, 1869, p. 242), says: "Many of the severer forms of late and visceral syphilis will require one drachm, or even larger doses, three times daily."

Hill and Cooper (London, 1881), in their work on "Syphilis and Local Contagious Disorders," p. 414, say, of the iodide of potassium: "Forty to sixty grains three times a day will sometimes quell an obstinate syphilide which has resisted smaller quantities, *but* larger doses than these may be required." I would also refer to my own book, published in 1883, p. 143, where the use of iodide of potassium in drachm doses in certain cases, and its continuance for a long period, is advised in the same connection; the method of its administration is distinctly indicated. At p. 199 et seq., a case of cerebral syphilis is cited in illustration, where drachm doses of iodide of potassium were administered for several months with apparent cure, and when the withdrawal of the remedy under other care, apparently, resulted in the death of the patient.

Inasmuch as, besides this, I have for the past twenty-five years taught this plan of treatment for the late lesions of syphilis in my clinic at the College of Physicians and Surgeons, and also for the past ten years in my wards in Charity Hospital, I would like to be included among those who were credited with having aided to some extent in spreading the knowledge of its great value in this country. I would like also to say that while there seems to me to be some question as to the good taste in claiming the plan of the administration of large doses of the potassium in cases of the late lesions of syphilis as an "American plan," there can be no question that it has found its earliest and warmest advocates and teachers among American physicians.

Dr. Seguin claims from personal inquiry that Dr. Draper recognized its value as early as 1865—nineteen years ago. In the same way, he states that Dr. Keyes recollects Dr. Van Buren as teaching it as far back as 1863—twenty-one years ago.

Dr. Taylor tells Dr. Seguin that he has accepted it ever since he heard it taught by Dr. Draper and Dr. Van Buren in 1866. This brings Dr. Seguin to the conviction that the plan is a purely American one, and was instituted by Dr. Van Buren. Dr. Seguin is in error.

Dr. William Kelly was Physician-in-Chief in Charity Hospital, Blackwell's Island, N. Y., from 1848 to 1853. He was a man of marked ability and thoroughly interested in all advances in medical science; and was an especial admirer of M. Ricord, and in harmony with his views on the treatment of syphilis.

In 1851 and 1852 I was an interne in that hospital, together with Professor Loomis (who is cited as approving the potass. iodide plan), also Dr. William Chamberlain, now one of the Visiting Physicians to Charity Hospital, Dr. J. W. Barstow, of Sanford Hall, Flushing, and others. The plan of treating the late lesions of syphilis with large doses of potassium was then in vogue in Charity Hospital, thus thirty-three years ago. Dr. Kelly, then Physician-in-Chief to Charity Hospital, was also a lecturer on Venereal Diseases at the College of Physicians and Surgeons, New York, at that early period, and taught the foregoing plan in the college and in the wards of Charity Hospital.

After Dr. Kelly's death his private case-books came as a valued legacy to me. Among the cases in book E., 1852, on page 6, I find the following: "Ulcers, syph. phagedenic, by large doses of iod. pot. Mary N—— was admitted to hospital February 14, 1851; had secondary eruption and enlarged glands and falling of hair in 1849. . . . At time of admission body was covered with ulcers, some rupetic and some ecthymatous. . . . Was put on generous diet, morphine, and iodide of potassium. This latter was carried up to two drachms per diem. Under this patient got apparently well, and was discharged September 1, 1851. Was readmitted to hospital one month after with ulcers on ankles. Periostitis of tibia occurred; surface over it ulcerated; treated with poultices and iodid. potass. Local applications—creasote ung., tabaci, nit. arg., etc.—failed to relieve pain. Iodide of arsenic was tried until its inefficiency was proved. Mercury in small doses. Patient all the time on ale and good diet.

"April 26, 1851.—Determined to try iod. pot. in large doses. The ordinary doses up to ʒj.–ʒij. had failed. The dose was then gradually increased, so that she took ℥ ss. of the salt each day. She began at once to improve. Pain ceased in two days, and healthy action of ulcers set in. She sat up for half a day on May 5th for the first time in four months. Now—May 11th—can sit sit up all day. Has taken six ounces of the iod. pot. to this date."

There are in the same book several other cases reported in full, which are in complete accord with the one quoted above, showing that this was the accepted practice in Charity Hospital at that time. I would then claim for Dr. Kelly the priority in systematically and successfully treating the late lesions of syphilis by means of large doses of the iodide of potassium and of teaching this method in public.

There seems to me an important difference of opinion between the editor of THE RECORD and Dr. Seguin, whose paper on the "Dosage of Potassium Iodide" was the original subject of comment, in regard to the best mode of administering the drug. Dr. Seguin states that a singular unanimity prevails among authorities in advising that the iodide of potassium should be taken *after meals* —he states that no good physiological reason can be given for this rule, and he says, "I strongly suspect that it is nothing more than the blind following after example." He therefore advises that it be always given upon an empty stomach. The editor of THE RECORD disagrees with him, and advises pursuance of the rule advised by authorities. The reason why the drug is usually given after meals is, I think, because it is less likely to produce irritation of the mucous membrane of the stomach.[1] It occasionally happens that, even when every possible care is taken, such disturbance of the stomach results that the use of the drug has to be discontinued. The life of a patient may depend upon his ability to bear a certain amount of the iodide. A very moderate experience with

[1] I have at present under my care a worthy and very intelligent member of our profession suffering with grave ulcerations on the throat from late syphilis. The original trouble was acquired in attending a syphilitic woman during confinement. The ulceration continued to progress until drachm doses of the iodide of potassium were taken every six hours. This amount (ʒj.) was administered *after meals* in an ounce of water, and followed quickly by a tumbler of milk. On being questioned yesterday as to the effect of these large doses on his digestive apparatus, he said, "My appetite and digestion are excellent. My stomach bears the iodide much better when taken after food. I do not feel the effect of *sixty* grains at a dose as much as I formerly did *fifteen* grains, well diluted, but on an empty stomach. The only time I feel any tendency to nausea is just after the dose I take at one o'clock A.M., when I follow it with a tumbler of milk, but on an otherwise empty stomach."

the use of the iodide of potassium in large doses will be sufficient to prove the increased tolerance to the drug when administered largely diluted with some bland fluid as milk, or some mucilaginous decoction; especially when administered after a meal. Beginning with eight or ten grains, the gradual increase, say by a grain or two (or even three in an emergency) at each dose, and taken with, or immediately followed by a tumbler of milk or gruel, preferably after a meal, has proved in my experience the most free from danger of irritating the stomach. I have recently had a case under my care where ʒ xij. were thus administered in twenty-four hours, for three months, without disturbance of the stomach, and with the effect of relieving almost completely a serious paralysis of the bladder and rectum, following constitutional or active syphilis. This is the largest amount I have ever administered in a case during the same time The assertion made by Dr. Seguin, that "*iodism is in nowise dangerous, and is only an inconvenience and a drawback to treatment*," is scarcely justifiable when a moderate amount of iodide of potassium will sometimes cause such irritation and swelling of the mucous membrane of the fauces and air-passages as to place a patient's life in peril. Such a case is quoted in Hill and Cooper, page 425, when tracheotomy was required to save life. I have myself seen the same accident, threatening death from œdema of the glottis, when only twenty grains of potass., thrice daily, were being administered.

MR. LAWSON TAIT AND LISTERISM IN OVARIOTOMY.

To the Editor of The Medical Record.

Sir: I have just seen in the columns of your valuable paper a paragraph headed "Another War over Listerism and Ovariotomy," in which you extract from Mr. Thornton's letter in the *American Journal of Obstetrics* certain figures which Mr. Thornton supplies on behalf of Dr. Bantock and myself. I can safely leave Dr. Bantock to deal with his part of the question. Concerning my part I can only say that I am not responsible in any way for any figures which Mr. Thornton may credit me with. So far as I can make out, Mr. Thornton's present figures are those which he manufactured for me on a previous occasion, and which require to be corrected as follows:

	Cases.	Deaths.	Mort. per cent.
Clamp (non-Listerian)...	36	9	25.0
Clamp (Listerian).....	26	7	27.0
Ligature (non-Listerian)..	209	6	3.0
Ligature (Listerian).....	30	2	6.6
	301	24	8.0

From this statement it will be seen by any one who can reason on the subject at all that so far as my practice is concerned Listerism has no effect one way or the other, and that the heavy mortality in the early part of my practice was due mainly to the clamp, assisted of course by the factor of want of experience, which always tells. Mr. Thornton lumps my non-antiseptic cases together, and ignores the fact that they contain this heavy clamp mortality. This he does, of course, because the question between us is as to whether it is the clamp or not which has been the root of all our evil. The suppression of the further dissection of my statistics which I gave is not honest, particularly after the discussions which have already taken place on this subject. The concluding sentence of your paragraph says that "it is known that Mr. Tait, when still a rising variotomist, was hardly treated with fairness by the London gentlemen whom he now in his triumph too rancorously assails." I am sorry that I am too rancorous on the subject, and for the future I shall endeavor to modify my expressions within limits which I trust may seem to you to exclude rancor; but if you knew in what manner I have been assailed, what vile charges have been made against me behind my back by Mr. Thornton and others, which they never dare even to hint at in public, you would, I think, agree with me that no kind of language could be too rancorous in dealing with such men.

Your obedient servant,

Lawson Tait.

P. S.—I am just closing my first thousand cases of abdominal section, and as soon as I can I shall send you a summary of conclusions, and after that I shall trouble myself not a brass farthing about Listerism or its advocates. L. T.

Birmingham, Eng., November 14, 1884.

TRACHEOTOMY IN CROUP.

To the Editor of The Medical Record.

Sir: In The Record of November 15th there appeared an interesting and forcible article by Dr. Simon Baruch, advocating an early operation in membranous croup, and giving as a basis for his argument the clinical histories of three cases. I cannot but dissent from the conclusions of the author, because I believe that, if tracheotomy were generally performed early in croup, many children would be unnecessarily subjected to it, and cures which would have been either spontaneous or the result of medical treatment attributed to it. To do the operation early one must often do it almost at the onset of the symptoms, for frequently only a few hours find the patient in great danger from asphyxia; while often the symptoms which have seemed so threatening as to warrant an operation may yield and the patient recover.

From choice or necessity, most operators do tracheotomy in cases of imminent danger, and are actuated, I think, more by the desire to relieve the patient, if only temporarily, from the fearful suffering which even they cannot witness with equanimity, rather than inspired by any great hope of saving life. I do not think that clinical experience bears out the belief that a late operation prejudices its success, for the patients seldom, if ever, die of exhaustion. The almost invariable history of those who die is that they succumb to an extension of the disease below the tube, or to the general effects of the disease, or worst of all, to the accidental stopping of the tube.

I believe, therefore, that while he who operates as a last resort occasionally saves a life, the early operator does the operation, in some cases at least, which would have recovered without it. I am greatly strengthened in this opinion by having observed several cases of membranous croup recover without tracheotomy, whose condition seemed most desperate. One expelled the membrane in a large cast, while in a hot bath into which it had been placed while almost completely asphyxiated, and two recovered under a plan of treatment which I will now describe, while giving the clinical history of the most recent case. I will premise by saying that the other case alluded to only differed from the one detailed in that the patient was a year older. Both were in a condition which would have justified an operation, and in both cases I am sure their cure, had it been done, would have been attributed to it. I was called to see the patient, a little girl, W——, two years of age, on the evening of November 15th, and found that she had been ill all the week, and croupy for two or three days. The parents had not considered her condition dangerous, however, until a few hours before I saw her, nor had any treatment been used. I found her breathing with the greatest difficulty, 50 to 60 a minute; the pulse, 140; and episternal and abdominal retraction well marked. Inspection showed diphtheritic patches upon the tonsils, and everything indicated a speedy asphyxia unless relief could be

obtained. I was deterred from advising an immediate operation by the fact that at two years the prospect of success is not flattering, and by a lingering hope inspired by the previous case, that the relief might perhaps be obtained by other means. I must confess, too, that, having done tracheotomy for croup seven times, with only one successful result, I am not as enthusiastic in its advocacy as I would be had I saved one in three.

To return to the case in hand:

I ordered equal parts of powdered alum and sulphur to be blown into the throat at the moment of deep inspiration (from an insect powder blower) as often as asphyxia threatened.

This was done, and the child struggled through the next thirty-six hours, expelling shreds of membrane after the insufflations at frequent intervals, until at length, on the fourth day, the respiration, though somewhat difficult, was much deeper and freer, and all membrane had vanished from the throat in view. The child has now been quite well for several days. I am not an enthusiastic therapeutist, and hardly thought of this as an efficient treatment for true croup, until this last and desperate case yielded to it.

What convinces me, or at least leads me to hope, that it may really be a means of combating the disease, is the fact that its use leads palpably and obviously to the expulsion of the membrane, and this makes the cure seem a logical sequence, rather than a lucky chance.

I desire expressly to disclaim any idea of originality in calling attention to this mode of treatment for croup, my only desire being to secure for it a fair trial. Let it be used, when used at all, freely and energetically.

THE VALUE OF HUMAN LIFE.—At the International Congress of Hygiene, at the Hague, Dr. Jules Rochard, of Paris, gave an address on this subject. He called attention to the commercial value of human life and to the loss occasioned by sickness and death; and then proceeded to consider the question, whether hygiene was capable of producing improvement. In doing so, he referred to the disappearance of diseases which once devastated countries. The black death, which destroyed a fourth part of the inhabitants of the world, forty millions in Europe alone, had become almost unknown; and many other diseases, to which our forefathers gave most formidable names, only remained in memory. In the same way, diseases of modern days ought to disappear. Already the occurrence of the plague was only sporadic; ague had still a few victims; but cholera still threatened. Small-pox, measles, and scarlet fever were all diseases against which protection could be afforded. This was best known in the case of small-pox; and he was convinced that the time would come when a father would be punished for having unvaccinated children in his house as much as for having dynamite or gunpowder in his cellar. The value of vaccination was beyond all doubt; and in America and England precautions had long been taken against measles and scarlet fever. By adopting proper methods, disease would be made to disappear. The speaker referred also to the researches of Villemin and Koch, in their bearing on the reduction of the mortality from pulmonary consumption. Severe legislation was not admissible; but care should be taken to prevent the marriage of phthisical subjects; to separate the phthisical from other persons in hospitals, dormitories, etc.; and to prevent the use of tuberculous meat. Endeavors should also be made to cause the disappearance of malaria by the drainage of marshes. In Holland, however, it was scarcely necessary to say this, for the whole country was a marsh, which through the courage and energy of the people had been dried and converted into beautiful valleys. He would not absolutely assert that all the germs of death and disease could be removed by sanitary measures. Hygiene could not entirely displace medicine. For, even when hereditary diseases disappeared, new diseases took their place; anæmia, diseases of the nervous system, alcoholism, morphinism, and many others which were the results of the vices of mankind.

IODIDE OF SILVER.—Dr. Sedan advocates the use of iodide of silver, especially in purulent affections of the eye. The salt is said to exceed in antiseptic power even the bichloride of mercury. The dosage is not given. —*Recueil d'Ophthalmologie*, November 8, 1884.

INHALATION OF THE VAPOR OF GLYCERINE.—Dr. Castle, of this city, writes concerning the abstract of an article in the *Revue Medicale* (MEDICAL RECORD, October 11, 1884), which refers to the benefit to be derived from the inhalation of vapor of glycerine by patients suffering from a fatiguing or painful cough. He thinks there must be some mistake about this, for glycerine is not volatile at ordinary temperatures, and when vaporized in the manner described, without the presence of vapor of water, it is very apt to be decomposed and give off acreolin, which would prove anything but comforting to the respiratory organs of the person subjected to the experiment.

JEWS AS PHYSICIANS.—Dr. C. H. Von Klein says in the *Journal of the American Medical Association*, that sixty-seven per cent. of Jewish physicians maintain professorships in medical colleges; thirty-six per cent. are medical authors. Medicine appears to be the favorite study, and, as a rule, they always maintain a high standing. There have been many Jewish physicians in a professional capacity at the courts of famous kings. The celebrated Maimonides was physician to King Salaheddin, of Egypt; Rabbi Meir to the King of Castile; Zedekiad, physician to Louis the Pious of France, and Montalto to Queen Marie of Medicis.

The Medical Record

Vol. 26, No. 24 NEW YORK, DECEMBER 13, 1884 Whole No. 736

Original Articles.

IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS?[1]

WHEN SHOULD THE OPERATION BE PERFORMED?

BY JOSEPH E. WINTERS, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, MEDICAL DEPARTMENT UNIVERSITY OF CITY OF NEW YORK.

At the March meeting of the Obstetrical Section of this Academy it was stated[2] that "tracheotomy is an operation attended with great immediate danger to the life of the patient."[3] This statement was so startling to me and so at variance with my impressions from reading, and from my own personal experience, that I believed it to be erroneous. The opinion that tracheotomy is a dangerous surgical operation I believe has no valid foundation, nor will it bear the test of a close examination, and should not be accepted with the confidence with which it seemed to be received in this hall last March.

The speaker, in the closing discussion, in corroboration of his opinion, quoted Mr. Timothy Holmes, of London, as saying that the operation is the most dangerous of any in surgery. On page 303 of Mr. Holmes' work on the "Surgical Treatment on Diseases of Children" will be found the following: "I think that, of all the operations which we are commonly called upon to perform on children, tracheotomy is the most dangerous, both in its immediate performance and in its secondary complications." And further, "I would not recommend tracheotomy while any prospect of recovery existed otherwise." If this suggestion of Mr. Holmes is followed, *delay* in the performance of the operation should be ascribed as the cause of both the secondary complications, and of death, rather than the operation itself. On page 302 he says: "In thirty-one cases the causes of death have been noted; and in *very few* of these cases was the cause of death connected in any way with the operation." . . . The original disease caused death in fourteen cases, "pneumonia and catarrh in twelve, scarlet fever in three, collapse of the lung in one, secondary hemorrhage (fifth day) in one," making the total number thirty-one, in none of which was the cause of death in any way connected with the performance of the operation, for Mr. Holmes states on page 326 that the ulceration which caused the secondary hemorrhage was produced by the tube. On page 316 he says: "Considering the risk of operating below the thyroid isthmus, and the large size and vascularity of that body at an early age, I would urge the propriety of making the opening above the isthmus. . . . After the age of five, or thereabouts, the surgeon can, if he prefer it, open the trachea below the thyroid isthmus. But I do not myself recommend this operation, at any rate before puberty." On page 318 it is stated: "To cut through the isthmus of the thyroid is, in early life at least, a dangerous proceeding."

Speaking of hemorrhage, Mr. Holmes, on page 317, says: "I have three times seen death on the table during tracheotomy; and twice from this cause. In one case, in which I was myself the operator, the child was very young (age not given). On exposing the parts, I dared not divide the centre of the thyroid body, on account of its thickness, and the large size of the vessels visible in it. On the other hand, to open the trachea below I had to *plunge* my knife almost beneath the sternum. . . . In the incision a vein was cut very near to its opening into the left innominate, and the bleeding proved fatal before I could get the tube in."

In the first volume of Trousseau, page 423, he says: "I have often witnessed the difficulties and dangers of a too nimble tracheotomy, even when performed by an able operator."

Marsh[1] says: "It would be nearly as reasonable to cut straight down upon the subclavian artery as to attempt tracheotomy as it is very often performed, and it would be scarcely more dangerous. The amount of hemorrhage during tracheotomy will depend almost entirely on the method of operating."

Mr. Durham[2] says that of one hundred and eight cases of tracheotomy at Guy's Hospital, performed during a period of twelve years, there was not a single case of serious hemorrhage, and the operations were performed by the house surgeons in a very large proportion of the cases, and that, too, very often under circumstances of peculiar emergency and difficulty.

Of eighty-seven cases reported in vol. ix. of *The Medical Times and Gazette*, collected from various London and provincial hospitals, there was but one case of hemorrhage, and in this Marshall Hall's tracheotome was used, and a vessel cut, ending in fatal hemorrhage. Durham says of this, that it is "an instrument which to mention is to condemn."

Regarding the thyroid isthmus, Trousseau[3] says: "If the isthmus of the thyroid body presents itself under your bistoury, never hesitate to divide it in the mesial line; there is usually an arterial jet as large as a thread, which ceases after some seconds, and by this section you have signally facilitated the operation." Of one hundred and nine tracheotomies for croup in children, Trousseau never found it necessary to have recourse to the ligature or torsion for a single vessel; the hemorrhage always ceased as the canula was introduced.

Holmes, on page 323, says the operator in trying to insert the tube into the trachea sometimes "pushes the canula down the cellular tissue in front of the windpipe, causing pressure on the trachea, and obstructing respiration still further." . . . "The third (case) in which I have seen death during the operation, the fatal event seemed to me due mainly to this error."

One of the three fatal cases of Mr. Holmes, then, was due to what Trousseau would have termed a "too nimble tracheotomy;" and in another, death was caused by pushing the canula into the cellular tissue outside of the trachea, and thus adding to the original difficulty. Comments on Mr. Holmes' tracheotomies are unnecessary.

The speaker then quoted Professor S. D. Gross as saying "the same thing" as Mr. Holmes. In Professor Gross' "Treatise on Foreign Bodies in the Air-Passages," on page 231, regarding tracheotomy in children, he says: "I know hardly an operation in all surgery that I would not rather undertake than this. . . . The amputation of a limb, the extirpation of a glandular tumor, lithotomy, and even the perineal section are *trifling matters* in comparison with tracheotomy in a

[1] Read before the Section of Obstetrics and Diseases of Women and Children, October 23d, and by invitation was reread before the Academy at large, December 4th.

[2] Dr. Ripley, MEDICAL RECORD, April 5, 1884, page 369.

[3] "The operation of tracheotomy in young children for croup, in its imminent peril to life, is one of the most dangerous operations in surgery." (Dr. Ripley, MEDICAL RECORD, July, 31, 1880, page 118.)

[1] St. Bartholomew's Hospital Reports, vol. iii., p. 334.

[2] The Practitioner, 1869, vol. ii., p. 212. [3] Trousseau in the Union Médicale.

short, thick-necked, and restive child." On pages 232, 233 he says: "The isthmus of the thyroid gland, even when it descends considerably lower than usual, will seldom embarrass our progress; should it do so, it must be held out of the way, although it has sometimes been divided with impunity."

He adds: "Professor Van Buren, of New York, informs me that he has completely divided this process on several occasions without the slightest loss of blood, mischief, or inconvenience." Even after this Professor Gross says: "Generally, however, it will be well enough to avoid it by holding it out of harm's way; should this, however, be impracticable, any *bleeding* that may be apprehended can be effectually avoided by embracing the part in two ligatures, the knife being *afterwards* carried between them." Here Professor Gross's directions certainly complicate the operation and prolong it unnecessarily.

He next directs that the trachea be held by a tenaculum.

The operation is performed with much more ease and safety when the trachea is grasped between the thumb and index-finger of the left hand than when held by the tenaculum. The trachea should never be entered without our being guided by the touch. If the windpipe is very deeply placed, and is not readily brought into view, it may be taken hold of with the double hook below where it is to be opened, and drawn upward and forward until brought into sight. The hook must, however, be held by an assistant, and the operator should keep his thumb and finger on the trachea.

On page 237 Dr. Gross says: "Great care is to be taken not to permit any blood to enter at the artificial opening, as the *smallest* quantity of this fluid may not only induce violent cough and spasm, but instant suffocation." Further: "The best plan to avoid this occurrence is not to injure any vessels, but to hold them carefully out of harm's way; or, where this is impracticable, *to wait until all hemorrhage has ceased before we penetrate the windpipe.*"

With reference to the first of these statements, it is known that the entrance into the trachea of a small quantity of blood is not dangerous, and many operators purposely introduce a quantity of fluid into it to excite cough in order to expel mucus and membrane. Bretonneau even recommended washing out the tube with a solution of nitrate of silver. Next to the hissing sound with which the air enters the opening in the trachea, one of the most striking things in connection with tracheotomy is the violence with which anything entering the trachea is ejected. To wait until all hemorrhage has ceased before opening the windpipe, would, in many cases, be to wait until the patient is dead. The surest way of arresting hemorrhage is to admit air freely to the lungs, so as to relieve the embarrassed venous circulation, and thus allow the blood to return to the heart. Time spent in trying to stanch the bleeding before opening the windpipe is generally to the injury of the patient.

With reference to this Professor Gross himself says on page 279: "It is worthy of remark that, when the hemorrhage is venous, it generally instantly ceases, even when it is *copious*, the moment the knife penetrates the windpipe." And again on page 266 he says: "I have never experienced the slightest inconvenience from any occurrence of this kind. Several of my operations, in fact, have been nearly bloodless."

Allow me to turn back and repeat a former quotation from Professor Gross, page 231, in order to make a comparison: "I know hardly an operation in all surgery I would not rather undertake than this. . . . The amputation of a limb, the extirpation of a glandular tumor, lithotomy, and even the perineal section, are trifling matters in comparison with tracheotomy." On page 373 he says: "I am satisfied, from the facts before the profession, that bronchotomy, properly performed, is, in general, a perfectly safe procedure, . . . *and rarely followed by fatal results.*"

Dr. Gross in his book does not report a case of tracheotomy for croup. After making a careful analysis of Dr. Gross' work, I am unwilling to accept his first statement regarding the dangerous character of tracheotomy, particularly when it is made to apply to the operation in croup.

Dr. A. Jacobi was quoted as saying that he never went to a tracheotomy operation without a feeling of fear and trembling. In the extensive writings of Dr. Jacobi on the subjects of diphtheria, croup, and tracheotomy, I fail to find any statements which would show that he considers the operation dangerous.

Now let us review the opinions of other authors:

Bretonneau, to whom we are indebted for the revival of tracheotomy in the nineteenth century, does not speak in any of his five memoirs of the operation as being a dangerous one, nor of skill in its performance being a necessity to insure success; his whole stress is upon the size of the canula, the temperature of the air the patient breathes, and the after-treatment and care. Bretonneau was so clear and decided in his convictions, which were always stated definitely, that had he felt the operation to be a dangerous one, he certainly would have mentioned it in one of his several communications.

Trousseau, whose contributions on tracheotomy have never yet been surpassed, said: "Tracheotomy in itself is an operation which is more delicate than difficult; it requires only care and presence of mind." He then says that he has performed the operation "more than two hundred times," and adds, "I have never had immediate accidents to deplore, except in an adult, who died of syncope at the *moment* I made the section of the skin." And again he says, "I have finished these operations, *apparently* so perilous, without fear and without accident."

M. Emangard[1] says: "The performance of this operation is exempt from all danger."

Rilliet and Barthez[2] say: "The operation in itself is not dangerous."

Bouchut, in 1852, said: "This operation is of easy execution—it presents no danger in itself, and if it does not succeed more frequently, it is because the cases in which it is employed are truly beyond the resources of art—the physician ought always to be ready to operate."

West says: "It is admitted on all hands that in itself the operation is not attended by serious hazard; and the uncertainty as to its issue depends not on any defect in the proceeding."

Meigs and Pepper speak in these terms: "*It is the uniform* testimony of those *experienced* in the matter, that the operation is in itself alone but *slightly* dangerous to life."

Vogel tells us that "the operation itself is not attended by any danger to life."

Dr. R. M. Edwards said:[3] "The operation itself is so simple to a man accustomed to handle a scalpel and forceps, that it is surprising so much has been written about it, and so many instruments devised to simplify its performance."

Dr. W. H. Day, of the Samaritan Hospital for Children, says: "Tracheotomy in itself is not a dangerous operation."

Mr. Lawrence[4] says: "We are fully justified in representing the operation of bronchotomy as attended with little pain and no danger." "The operation itself is so simple and so easy that there is very little to be said on the mode of executing it."

Conway Evans[5] says: "That tracheotomy is in itself a very dangerous operation, the tendency of all evidence on the subject tends to disprove." He quotes from Professor Gross' work to show that the operation is not dangerous!

J. H. Pooley, M.D., Professor of Surgery, Starling

[1] Les Annales de la Méd. et Phys. Sep., 1827. [2] Dis. of Children, vol. i., 386.
[3] In the Edinburgh Med. Journal, October, 1856, vol. ii., part 1, p. 314.
[4] Med. Chirurg. Trans., vol. vi. 1815.
[5] Edinburgh Med. Journal, January, 1860, vol. v., part 2, p. 623.

Medical College,[1] says: "The operation itself involves very little danger to life."

Wm. M. Mastin,[2] in an article in which he gives an analysis of eight hundred and sixty-three tracheotomies which he collected with much care, says: "I cannot see . . . how any one will venture to say that tracheotomy is *per se* of particular danger."

Mr. Howard Marsh,[3] in an article entitled "Tracheotomy in Children, its Method, its Dangers, and its Difficulties," says: "I am convinced that tracheotomy should be regarded as a delicate operation, which requires coolness and caution in its performance, rather than as one that is necessarily either very difficult or very dangerous."

Robert Wm. Parker, Assistant Surgeon of East London Hospital for Children, says: "By *common* consent the operation itself is not dangerous, and it hardly, if at all, complicates the primary disease which calls for it."

Thomas King Chambers said: "Tracheotomy is an alarming operation to hear of or to look at, but in reality it is not a dangerous one. . . . Do not, therefore, alarm the patient's friends by speaking of it as a 'last hope,' 'a final resource,' or by any similar weak, expression."

Let us see what was the verdict of the older authors on this operation. They always spoke from the force of their convictions, and in definite, unmistakable terms.

According to Galen, Asclepiades first invented and performed tracheotomy in cases of quinsy, about 100 B.C. Here the term "quinsy" relates to croup of the present day, for it is described as an affection which "presents no visible appearance either in the swallow or in the throat, which, while narrowing the glottis, renders the voice acute, and quickly manifests symptoms of strangulation."

Cœlius Aurelanius says: "In this manner he (Asclepiades) saved a great many persons who were in danger of perishing from suffocation."

Fabricus, in the sixteenth century, said: "The operation is absolutely free from danger. . . . There is no part of the least consequence exposed to injury in this operation." Fabricus is the first who speaks of the canula.

Casserius said: "Those are both ignorant and timorous who rashly neglect this safe, easy, and often salutary operation. It is easily performed, and cannot give rise to danger. . . . We have nothing to fear from the slight hemorrhage caused by opening the trachea." Casserius, who introduced the curved canula, is the first who mentions the thyroid gland in speaking of the operation.

In 1586 Sanctorius proposed puncture of the trachea with the trocar, which he had invented for performing abdominal paracentesis.

Bartholini entertained doubts respecting the use of the operation in quinsy, especially in infants.

René Moreau, in his reply, March 1, 1646, declared that the operation was neither difficult nor dangerous, and through his sound reasoning he served to convert Bartholini to the use of the operation.

In 1695 Dekker proposed to perform the operation with a cutting trocar.

Boerhaave,[4] in the first part of the eighteenth century, said: "The windpipe may be divided without any danger to the patient's life."

Detharding, in 1714, wrote, with reference to tracheotomy: "The skin only is divided, and a small portion of membrane. There is no ground for fear, even from the least dexterous operator. No blood-vessel from which one need fear hemorrhage, no nerve of which the division can produce any inconvenience."

Juncker, in treating of this operation, said: "It does not require great dexterity." The first vertical incision through the cartilages of the trachea was made by him.

In 1750 Dr. Lawrence Heister,[1] Professor of Physic and Surgery in the University of Helmstadt, wrote: "This is a safe, easy, and often salutary operation." Heister was the first to use the word tracheotomy.

Louis, in the early part of this century, said: "A little consideration as to the parts to be divided and the mode of doing it suffices to show that the operation could not be attended with the least danger."

Mr. Holmes' obvious misconception regarding the performance of tracheotomy, and the contradictory statements made by Gross, show sources of fallacy on their part; and this, with the vast preponderance of authorities against their opinion, wholly overthrows it.

The operation of tracheotomy not being dangerous in itself, nothing connected with its mere performance should influence the time when it is to be resorted to.

How does diphtheria tend to cause death when left to itself? In a very large proportion of the fatal cases, the disease, in young children, ultimately causes death by mechanically obstructing the passage of air into the lungs. The object of tracheotomy is to supply a provisional air-passage in the place of the obstructed rima-glottidis, so as to allow the disease to run its full course, and to gain time for the administration of remedies; and if it accomplish this, it should be acknowledged, even though the patient should die afterward from the persistence of the original disease, or some of its complications. That it does accomplish this will be seen by the mode of death after the operation. This depends very much upon what time in the course of the disease the operation has been performed; the type of the disease, the condition of the patient, and the care with which the after-treatment has been carried into effect. When the operation has failed to save life, it has been generally either because it was postponed until it was too late, until secondary complications in the bronchi and lungs have arisen, to sudden collapse, to the persistence and extension of the original disease, causing death by asthenia or acute nephritis and uræmia, or because efficient after-management and care were wanting. Suppuration in the anterior mediastinum (this generally may be obviated by not extending the superficial incision too near the top of the sternum), erysipelas and gangrene around the wound, and the slipping of the canula from the tracheal opening have been experienced.

I wish you to mark that none of these causes of death are instances of failure of the operation when properly performed, or of its not removing the main source of danger when the disease is left to itself.

The only lesion that causes death, which is directly due to the operation when properly performed, is ulceration of the trachea from the mechanical irritation of the tube.

Vidand, in 1854, and Goupil, in 1856, exhibited before the Anatomical Society of Paris two specimens of ulceration of the trachea after tracheotomy, produced by irritation of the canula.

In 1859 Barthez called attention to this point, still almost unknown.

Roger, in the same year, in a monograph, published an analysis of twenty-one cases of ulceration of the trachea.

Sanné[2] in his work reports seventeen cases, collected in the service of Barthez. He says: "More or less redness of the trachea and bronchi have been noted in eleven of seventeen cases, out of which seven were accompanied with broncho-pneumonia. In one case there was abscess of the mediastinum, consecutive to a perforation of the posterior wall of the trachea, and one of œdema of the glottis."

In the Trans. Path. Soc., London, vol. xviii., p. 32, is recorded a case of death from pyæmia after tracheotomy, from ulceration caused by the tube. Two cases have happened in Guy's Hospital, in which ulceration extended through the anterior wall of the trachea into the innominate artery, and fatal hemorrhage of course resulted.

[2] Sanné: Étude sur le Croup, apres la Trachéotomie.

Mr. Marsh reports two instances of ulceration of the trachea out of thirteen operations in his own experience, and makes allusion to three others he has been told of.

There are many cases scattered through the literature on tracheotomy, but these are sufficient for us to recognize its importance, its frequency, and the different ways in which it tends to cause death.

The causes are the shape, the size, and the length of the tracheal tube, so that it presses against the walls of the trachea to the extent of producing mechanical irritation and ulceration.

Roger thinks that a small canula, by allowing of its too free movability and the consequent friction which results from it, can cause ulceration.

The symptoms are expectoration of more or less pure blood, along with the sanguinolent expectoration common to every case of tracheotomy for the first few days, in some cases pain referred to the point where the tube impinges against the wall of the trachea, and dark discoloration of the end of the canula.

The accident can almost always be prevented by having the canula short, curved at nearly a right angle, and of proper size, so as to fit quite accurately the calibre of the trachea, but without making undue pressure, and having it freely movable on its shield, so that it shifts with the varying attitudes of the child. The tube should be carefully watched and the trachea daily examined for indications of irritation, and if detected, the tube must be removed and the opening in the trachea kept open by means of silver or hard-rubber or gutta-percha hooks, which are held in place by a tape going around the neck.

Tracheotomy, then, perfectly accomplishes its primary object—that is, to overcome a positive mechanical obstruction in the larynx, and to prevent that mode of death by which nearly all fatal cases of diphtheritic croup, in which it is not resorted to, terminate, namely, death by asphyxia.

We will now consider

The influence of the operation on the original disease.—Sir James Paget[1] says: "I have never seen the wound become diphtheritic after tracheotomy." Further on he says[2]: "I have collected the particulars of upward of one hundred and twenty cases in which tracheotomy was performed in children suffering with diphtheria, and in none of them was the wound attacked by the disease."

Mr. Spence, in a letter to Sir James Paget, wrote: "I have, on several occasions, seen the wound affected, and have known the child die from that, after the breathing was free and the tube removed." He does not in this communication state, however, whether or not the disease had disappeared from the fauces; in other words, that death was not due to the persistence of the original disease, at its original site.

Mr. Parker, of London, says: "In my own practice it has only occurred twice, and on each occasion it was very slight. In one case, on removing the tube, I found the wound patched over with little islands of false membrane. . . . In another case a similar condition of the wound was found."

Mr. Howard Marsh says: "Diphtheria of the wound is rare."

Trousseau says he has seen leech-bites, slight cuts, blisters, and excoriations and different wounds in various parts of the body became diphtheritic, but he does not speak of its occurrence on the tracheal wound, which, from his usual careful minute way he surely would have done had he ever observed it.

Sanné,[3] who was a pupil of Trousseau, and who bases his observations on six hundred and sixty-two operations on croup by tracheotomy, says in his excellent work: "Diphtheria of the wound is not so frequent as you might at first suppose. It seems that the false membrane appears more readily on the cutaneous ulcerated surface, or that only deprived of its epidermis, than in a wound which involves the profound parts. This is so commonly the case that in diphtheria of the wound the lesion is first to be seen on the superficial parts, or edges of the wound, where the skin has been cut. It then extends to the neighboring parts." . . . "I will not advance, however, that diphtheria never attacks the edges of the wound, . . . but I do insist on this point, that very often the pellicles of the wound have been confounded with plastic exudations." . . . "Diphtheria of the wound by itself is not very grave; of all the complications which belong to the wound it is the most natural, since it is but the propagation to the exterior of the lesion which characterizes anatomically the malady; it has then in a great many cases but a local importance."

I had expected in examining the German authorities to find frequent mention made of diphtheria of the wound, on account of their proneness to call every wound on which there is an exudation diphtheritic. I find, however, that their references to it are very infrequent, that it is always found to be very slight, and does not complicate the original disease or the operation, and that it is readily controlled by simple treatment.

Dr. O. Pinner,[1] in a report of one hundred and thirty-seven cases of diphtheria and tracheotomy says: "In a few cases diphtheria of the wound occurred."

Dr. Max Schüller[2] says in his work: "As a rule diphtheria of the wound may be prevented entirely by the early employment of damp carbolic dressings." . . . "At any rate it seldom becomes necessary to employ energetic remedies, as diphtheria of the tracheal wound does well under carbolic treatment."

Dr. H. Lindner[3] says: "Diphtheria of the wound occurred in but three of one hundred and one cases operated on. Gauze compresses of carbolic acid was the only measure taken to prevent its occurrence."

We now come to

The influence of the operation on the cure of croup.—The admission of air into the lungs through an artificial opening in the windpipe secures for the diseased larynx entire rest, and this leads to a suspension of diseased action there. Even if the patient die after the operation, and we find, *post-mortem*, that the diseased action has not ceased in the larynx, it is generally either because the operation has been too long delayed, and, as a result, death followed too soon for any reparative process to take place, or to the character of the original disease.

Mr. Spence's communication to Sir James Paget shows that the cure of croup may be accomplished by tracheotomy during the persistence of the orginal disease, and which afterward may destroy life.

The following cases from Sanné's interesting work are most instructive, and confirm the statement that tracheotomy tends to the cure of this very fatal complication:

Case IX., page 202.—Aged four years; operated on in second stage of croup. Died third day from exhaustion. Autopsy showed that the larynx contained no false membrane.

Case XI., page 208.—Aged five years; operated on in third period. Died sixteenth day. Larynx swollen and œdematous, but contained no false membrane. Died of Bright's and pulmonary complications.

Case XII., page 213.—Aged eighteen months; operated on in third period. Died fourth day. No false membrane in the larynx. Bronchi contained a quantity of detritus and false membrane. Marked congestion of posterior part of the lungs.

Case XIII., page 214.—Aged five years. Tracheotomy third period. Died eleventh day. No false membrane in larynx; right lung healthy; left lung seat of pneumonia.

Case XXVII., page 252.—Aged twenty-three months;

[1] Second edition of his Clinical Lectures, p. 24.

operated on in extremis. Death eleventh day after operation. No false membrane in larynx.

Case XXVIII., page 256.—Aged two years; operated second stage of croup. Died one hundred and fifty-fourth day. Nothing in larynx.

In every recorded case in which death occurred within twenty-four or forty-eight hours after the operation, false membrane was found in the larynx on autopsy.

In "Guy's Hospital Reports," Third Series, volume xxii., the autopsies in cases of croup show the same results as those given above.

Some interesting cases bearing on this are found in *The Medical Times and Gazette*,[1] in an article entitled "Comments on Tracheotomy for Scald of the Glottis." There were three cases which ended in recovery. The ages of the patients were one year, two and a half years, and three years, respectively. "It would appear that when cases do well after tracheotomy for this accident, that the restoration of a healthy condition of the laryngeal mucous membrane is rapid. In one case the canula was kept in place for six days, in another for five, and in a third for three."

The following case from "Guy's Hospital Reports,"[2] with remarks by Mr. Howse, shows still more strongly the value of tracheotomy in the cure of laryngeal disease: A child aged twenty-six months, with chronic laryngitis. Breathing stridulous. Tracheotomy performed by the house surgeon October 8th, died on the night of the 12th. Autopsy showed the larynx and epiglottis to be normal in appearance.

Remarks by Mr. H. G. Howse, one of the editors of the "Reports:" "The normal appearance of the larynx is of great interest, as it tends to show that when the part is put in a state of perfect rest after a tracheotomy operation, all signs of inflammation may subside within five days—the period which elapsed between the operation and death."

The cure of many cases of ulceration of the larynx by tracheotomy, occurring in the course of pulmonary phthisis, and which return after the tracheal opening is allowed to close, but again subside when the functions of the organ are once more suspended, might be quoted if time and space permitted.

The influence of tracheotomy in arresting diseased action in the larynx, leads us quite naturally to contemplate the relation of laryngeal to laryngo-tracheal diphtheria. The diphtheritic process stops at the level of the vocal cords much more commonly than is generally supposed. That this is true of a large percentage of the cases is shown by some valuable autopsies recorded by Krönlein.[3] Of 200 autopsies reported by Krönlein, in 46 there was false membrane in the *larynx and trachea;* and there were 164 with membrane in the *larynx* and on the parts above, and *no membrane in the trachea.*

When the disease involves the trachea it is by *propagation from the larynx, and not by a simultaneous attack on the larynx, trachea, and bronchi.* In many cases this *extension downward may be prevented* by early making a way for sublaryngeal respiration, so that the inflamed larynx may be allowed to rest and be saved from irritation by the passing breath, and thus cause the arrest of diseased action there.

If tracheotomy *per se* is not dangerous, if it meet the complication of obstruction of the glottis, and is promotive of the cure of this complication; if the specific disease is in no way aggravated by it, and very rarely indeed appear on the wound, it certainly brings with it no element of added danger.

Influence of delay.—The next consideration in deciding when to operate would be the result to the patient of delay in the performance of the operation. When we see that medicinal remedies fail to influence the arrest of croup, to relieve, or even to alleviate its symptoms, shall we trust to the occurrence of that rare accident, the expulsion of the membrane, or shall we operate without delay?

As to expectoration of the membrane and cure of the disease without operation, Professor J. Lewis Smith stated at the March or April meeting that about one in eight recovered when medicinal treatment only was used. Statistics of croup (membranous), taken collectively, show that the disease is fatal in about ninety per cent. of the total cases.

After tracheotomy the recoveries are from one-fourth to one-half. Trousseau gives one-third in hospital, and one-half in private practice. Collected statistics from English and Scotch hospitals and private practice show that two-fifths recover after the operation.[1] Sanné[2] gives 89 operations by eleven different operators in various parts of France, with 39 cures: one cure in 2.28 operations. In another table, 39 operations by five operators with 17 cures: one cure in 2.29 operations. These figures at once decide clearly the only course to pursue.

Does delay in the performance of tracheotomy compromise its success? I cannot conceive a case where delay would be more dangerous; there is constant risk of suffocation, which sometimes comes on very suddenly. We gain nothing by delay, while the success of the operation is interfered with to a great extent. When the rima glottidis is obstructed less air enters the lungs with every inspiration, and the lungs are less expanded, and in proportion as the circulation of air through these organs becomes diminished, the circulation of the blood will be embarrassed, and this soon causes this fluid to become vitiated by defective oxygenation. When the operation is long delayed the impeded state of respiration and circulation produce a violent constitutional disturbance; venous congestion has become general, the veins of the head and neck are turgid, the entire body cyanosed, cold, and bathed in clammy perspiration, the pulse at the wrist imperceptible, the face livid and ghastly, the child tossing in agony from one position to another, hoping to find relief, the inspiratory muscles, especially the auxiliaries, making violent, but fruitless efforts to get more air through the contracted glottis. The vessels of the bronchial mucous membrane and the lungs become passively distended, and a little later serum infiltrates into the parenchyma of these organs, and the bronchi become choked up with mucus, thus impeding respiration still further. The weakened and overtaxed heart, with the brain, being supplied only with venous blood—the patient, in fact, poisoned by his own vital fluid—becomes comatose or convulsed, and the sensorial functions blunted and nearly destroyed. Yet it is advised that the patient be allowed to reach this stage, that the immediate precursors of death appear, before making an opening in the windpipe to allow the passage of air to the lungs!

If under these circumstances the operation fails to save life, it is spoken of as being dangerous and perilous, of inducing secondary complications, and similar absurd expressions!

It would be as rational to persist with taxis in a strangulated hernia until gangrene has set in, before relieving the constriction with the knife, as to continue medicinal treatment in a case of obstruction of the glottis until the patient has arrived at the stage described, before making an opening for sublaryngeal respiration. And in the same proportion that delay in strangulated hernia is dangerous, so it is in a case of membranous obstruction of the glottis.[3]

He who has made autopsies in cases of croup where tracheotomy has not been resorted to, and death has oc-

[3] Justice to my patient, justice to myself, fidelity to the profession I represent, all unite in demanding that *more*, early, before the development of conditions which will make any interference but a forlorn hope, tracheotomy should be done! (L. S. Pilcher, Proceedings Kings County Society, Brooklyn, May, 1877, p. 82.)

curred from asphyxia, has seen that the lungs and bronchi are in a state of venous congestion.

My own records show this invariably. I have examined the records of a large number of autopsies and have found that, where carefully made and recorded, the appearances were quite uniformly the following:

First, where tracheotomy had not been performed, the lungs and bronchi were congested, and there was *always* an excessive quantity of mucus on the bronchial mucous membrane. In a smaller number of cases, œdema of the lungs and pneumonic changes.

Second, where tracheotomy had been performed in the third stage of croup, and death had followed soon after, the post-mortem appearances were much the same as in the cases not operated on.

Third, where death had taken place from several days to two or three weeks after the operation, the mucous membrane of the bronchi and the pulmonary vessels was quite normal.

Showing how quickly obstruction to respiration may induce changes in the bronchi, Mr. Thomas Bryant[1] relates the case of a child three years old, in whom tracheotomy was performed for foreign body, and it could not be removed. The operation was performed one hour after the accident. The respiration remained unaltered, and nine hours after the operation, and ten after the accident, the child died. On autopsy, the bronchial tubes were found filled with tenacious mucus—in some parts completely obstructing the passage of air to the lungs, which were *airless*. A piece of nutshell was found in the rima between the cords.

The condition of the pulmonary and bronchial vessels, found so constantly after death from croup, results from obstruction in the larynx and impeded respiration, for when diphtheria exists in the throat only, and there is no implication of the larynx, the disease tends to destroy life by exhaustion and blood-poisoning, and rarely do any of the secondary bronchial or pulmonary complications occur.

Where these complications are found on post-mortem examination, after tracheotomy, they are not the result of the operation, for they seldom occur when tracheotomy has been performed on healthy organs, or in cases of syphilitic, and even tubercular laryngeal disease, with chronic pulmonary disease, and the tube is worn for months, and in some instances for many years. The repeated performance of the operation on the same patient within a short period, without accident or complication, and with ultimate recovery, shows the utter harmlessness of tracheotomy, both in its immediate effects and in its remote consequences.

Mr. Greenfield[2] relates that tracheotomy on a child ten months old, with croup, was repeated nine days after the first operation, and seven days after the removal of the tube by the nurse. During the latter part of this operation the child appeared to be dead. Artificial respiration was performed and the child revived. Recovery was perfect. Dr. H. Z. Gill[3] performed two operations of tracheotomy on a boy, aged three years and one month, with croup, at an interval of fifty-one days, with ultimate recovery. No bronchial or pulmonary complications after either operation. Pugin Thornton[4] performed tracheotomy four times in five years on a man sixty-seven years old, with syphilitic laryngitis, without accident or subsequent complication, and the case ended in complete recovery.

The great reason why bronchial and pulmonary complications follow tracheotomy where it is performed for croup is, that where obstruction has continued a long time the lungs are in a state of congestion, and in this condition any slight irritating cause, such as would act harmlessly on healthy lungs, will hasten on into a dangerous inflammation. When it has been decided that a positive mechanical obstruction to the entrance of air into the lungs exists, do not wait until lividity sets in, before making a way for free and easy respiration. Let the operation be done before secondary complications have arisen, or the accession of those symptoms which are in themselves extremely dangerous to life, which often render all treatment unavailing, and make the removal of the mechanical obstruction of less importance.

While estimating the effect of protracted obstruction to respiration with the devitalizing influence on the blood of the rapidly accumulating carbonic acid gas, its depressing action on the organic nervous system and on the heart, we should keep in view that these combined influences are promotive of the spread of that depressing disease, diphtheria.

We must also take into consideration the life-giving and disease-destroying power of oxygen. Oxygen is the most potent of all tonics, and pure, warm air is the most valuable remedial agent that we possess for diphtheria. Let a child with severe diphtheria be kept literally out of doors, in warm, dry, sunny, summer weather, and an almost immediate and uninterrupted improvement in all the symptoms will be observed, both in the general condition and in the local manifestations. In the majority of cases of croup the patient dies from want of oxyger. and exhaustion of the organic nervous system; and the object of the tracheotomy is to render oxygen accessible to the child; and it should be remembered that every draught of fresh air assists in the process of cure. Do not wait, therefore, until the patient's strength is worn out with gasping and fighting for breath before granting him nature's sovereign restorative.

Who can watch a child struggling for breath with all the agony which in consequence ensues without feeling impelled to have recourse without delay to the simple procedure of tracheotomy? Let those who counsel that tracheotomy be the last resort witness the extraordinary relief which follows it, how the breathing becomes tranquil, easy, and regular, the countenance natural, the cold sweat ceases, the pulse is again felt at the wrist, and perhaps the child sits up and takes nourishment, or falls into a quiet, peaceful sleep; and I think they will regret not having granted the child access to air sooner, and lifted in one instant an agony of suspense from the parents!

Guersant ascertained that the resolution of pneumonia is facilitated by the greater freedom with which the respiratory functions are accomplished after tracheotomy. But while the symptoms of suffocation and of pneumonic changes may be relieved by the late performance of tracheotomy, they may often be *prevented* by the early introduction of air into the lungs. It is said that if we advise early operation we may operate on many who would have recovered without resource to this proceeding; and that we may see our patient recover after the operation has been rejected by the parents, but this will happen very rarely indeed, and it is better to err on the safe side, as the operation can never increase the danger, while delay has many times deprived the patient of that chance of life which the operation can offer.

Though there are, undoubtedly, isolated cases of recovery from diphtheritic croup, the proportion of these is so small after we are *positive* that membranous exudation has invaded the larynx, that we ought to have early recourse to the only mode of arresting death in the majority of cases.

It is a far weightier responsibility to decide when to operate than merely to open the windpipe. We must first determine the existence of false membrane in the larynx.

Though recession of the soft parts of the chest-walls with every inspiration is a valuable test of the amount of interference with that act, it does not necessarily indicate the presence of a pseudo-membrane in the larynx, and it is not a reliable guide if the expiration is free and easy, for these symptoms may be due in great part to spasm. The dyspnœa due to spasm alone is intermittent or remittent, never continuous. But if

[1] Guy's Hospital Reports, Third Series, 1860, vol. vi, p. 13.
[2] St. Thomas' Hospital Reports, vol. viii., p. 263.
[3] Illinois State Medical Society Transactions, 1878, p. 167.
[4] British Medical Journal, February 17, 1877, p. 205.

there is suppression of the voice, and expiration is labored, prolonged, and audible, there is no longer doubt about the presence of membrane, for nothing but mechanical obstruction could produce these symptoms. As soon as they appear, and there are no longer remissions between the croupal paroxysms, but the dyspnœa is continuous; if insufflations of alum, or of alum and sulphur, with ipecacuanha cease to afford relief, or emesis can no longer be produced, and if ipecac only purges, and poultices and steam have been fairly tried, it may be said that all remedial measures have failed to control the disease, and the operation should at once be performed.

There is nothing in the operation itself incompatible with recovery, even at the early age of six and nine weeks. In 1830, Dr. Scoutetten, Professor of Surgery, Military Hospital, Strasburg, operated successfully on his own child, six weeks old.

The diagnosis of croup in this case has been questioned, but it is stated in the original report that there was expectoration of membrane for two days after the operation.

In 1880, Dr. Steinmeyer[1] performed a successful tracheotomy on a child nine weeks old. I have during this research found recorded an astonishing number of recoveries from tracheotomy in infants from a few months to two years old, which shows that the tender age of the patient should not be allowed to contra-indicate tracheotomy; and the recollection of these may induce many to perform the operation who now oppose it on the ground of the early age at which we are frequently called upon to have recourse to it in many cases of diphtheritic croup.

In very young children the disease advances much more rapidly, and the liability to bronchial and pneumonic complications is greater, and they come on earlier in the disease than they do in older children, therefore we should operate earlier in the younger. In young children the trachea is deeply imbedded in cellular tissue and fat; it is small and freely movable, and the other structures of the neck are closely connected with it. Thus the operation presents *difficulties* which are not met with in older children.

Prognosis.—Early age, previous ill health, especially chronic catarrh, scrofula, bronchial and chronic pneumonic changes, all make the prognosis more serious. If scarlet fever or measles are prevailing at the time of the operation, and the patient has not had them, he contracts them with increased facility, and the prognosis is rendered very grave by this added danger. Nasal diphtheria makes the prognosis worse and severe epistaxis before or after the operation is of bad prognostic omen. When croup comes on very early in the disease, and makes its appearance very suddenly, and the obstruction is at once extreme, the prognosis is far more serious, for in such a case the membranous exudation early tends to spread into the bronchi, and even to the alveoli. When the lymphatics of the neck are much enlarged, and the neck greatly swollen, the operation has less chance of success. The presence in the urine of albumen and casts make the case more unfavorable. When the breathing is very laborious in character, and the supra-sternal, supra-clavicular, infra-clavicular, and the scrobiculus cordis depressions are not marked, the prognosis is less favorable than when recession at these places is very considerable.

When the bronchi and lungs are free, and the obstruction to inspiration is only in the larynx, the recession of the soft parts is very great. Less marked depression denotes obstruction below the larynx and the existence of secondary complications.

It is an unfavorable sign if the breathing does not become perfectly free and regular after the operation, and indicates either the existence of false membrane below the tracheal opening, or a large quantity of mucus in the tubes, or pneumonic changes. Difficulty in swallowing after the operation is a bad symptom. This arises from fluids passing through the glottis, where they excite convulsive coughing and escape through the canula.

After-management.—Success after tracheotomy is to be obtained more by careful nursing than from the perfection of the operation itself. From careful observation I am convinced that the two main causes of failure of tracheotomy in saving life are the late performance of the operation, and inefficient after-care, and among the last-named want of proper attention to the canula. Obstruction at the inner end of the tube from false membrane or mucus, causes more deaths after tracheotomy, than either pulmonary diseases or the original malady which rendered the operation needful.[1] The physician should not forget that his whole duty is not performed when the operation is completed; that tracheotomy does not tend to *cure* the disease, but that it allows time for the application of the treatment found to be most successful in controlling it.

The sustaining of the patient, the administration of the remedies for the arrest of the disease, attention to measures for subduing the local process and reducing inflammation, the temperature, quality, and amount of moisture in the air that the patient breathes, the care of the canula, and the condition of the trachea and bronchi are not generally carried out with enough thoroughness to give the patient all the advantages which the operation is capable of affording.

I must again revert to the most important of all the questions just now in connection with our subject—the danger of the operation itself. The quotations from so many eminent authorities of vast experience in the performance of tracheotomy prove beyond all peradventure that the opinion that it is a dangerous operation is erroneous—and it is not only erroneous, but dangerous. To the majority of people in this city the proposal of tracheotomy seems equivalent to pronouncing sentence of death; and from the operation being represented as formidable comes the unwillingness of parents to consent to it until the child is about to expire, and of physicians to undertake its performance.

In many cases where tracheotomy is required it is as much a case of emergency as that of a bleeding artery. When danger is imminent, an operation is often needed even without a consultation, and a delay of a few minutes might cost the life of the patient; but owing to the practitioner being afraid to operate, he often leaves his patient struggling for breath and rushes after a *tracheotomist*, and returns, perhaps, to find that his patient has died strangulated.

At the March meeting one of the speakers said that he had been summoned to half a dozen such cases, and then, in alluding to the danger of tracheotomy, he stated that he "was willing to go upon record as saying that there have been more deaths upon the table in tracheotomy than from any other operation which is performed."[2] From this he inferred its danger! It would have been as logical to have said that tracheotomy is dangerous because more patients have died during the delay attendant on the bringing of a tracheotomist to the patient.

An eminent physician in the early part of this century was allowed to perish from this very neglect. Dr. Matthew Baillie in the third volume of the "Transactions of the Society for the Improvement of Medical and Surgical Knowledge," records the fatal illness of Sir John Macnamara Hayes. He was taken ill on July 16, 1809. His disease was croup. On the night of the 18th tracheotomy was proposed. Mr. Home and Mr. Wilson were sent for to perform bronchotomy. Mr. Wilson was out of town, and Mr. Home did not come until four in the morning, but the patient was then in a dying state; he expired at six. Autopsy, 20th: "The cavity of the glottis was found to be almost obliterated by the thick-

[1] Berlin. klinisch. Wochen., No. 46, 1880. Operation for retro-pharyngeal abscess.

[1] Seventy-eight per cent. die in the first four days (Wanscher). Seventy nine and one-half per cent. die in the first four days, and nearly sixty-three per cent during the first two days (Krönlein, in Langenbeck's Archives).

[2] Dr. Ripley, MEDICAL RECORD, April 5, 1884, p. 388.

ening of the inner membrane of the larynx at that part." A prominent practitioner in this city left a case of diphtheritic croup in the care of a young surgeon, who had been on the surgical staff of Bellevue Hospital for eighteen months, with the instruction that he should go for Dr. X. if he thought tracheotomy necessary. It did become so and he obeyed instructions. Dr. X. not being at home, another surgeon was sought and found. The trachea was opened immediately, but the child died soon after from exhaustion, owing to the late performance of the operation.

Contrast this absurd proceeding with the custom in the hospitals in England, where nearly all the tracheotomies are performed by the house-surgeons.

In this connection the action of Professor J. G. Ehrhardt,[1] in the light of a single experience of the kind, is interesting and instructive: "Case of diphtheritic croup, summoned at 2 P.M., December 12th, and found child much worse. Tracheotomy only thing that offered benefit. Time was lost while waiting for my father to assist me, when he arrived the boy was nearly dead. There were two or three respirations after the tube was inserted. I do not believe that the operation hastened death." "December 15th, called to a boy of five years. Time was too precious to send for a surgical assistant; operated at once. Child recovered."

The physician who leaves his patient in a state of rapidly advancing asphyxia and goes in quest, perhaps in vain, of a surgeon merely to make an opening in the windpipe, is as culpable of neglect as he would be if he left a spurting artery and went for a surgeon to arrest the bleeding. Another reason why an exaggeration of the danger of tracheotomy should not prevail is that in country districts it almost entirely prevents recourse to it. A physician but eighty miles from this city, who is in the habit of doing capital operations, has told me that he would not dare to undertake tracheotomy, because there is a *universal* impression that the operation is extremely dangerous to life.

I hope, as a result of the proper appreciation of this life-saving measure, and a thorough understanding of its harmlessness, that when diphtheritic croup is epidemic in the country, tracheotomy will be as frequently performed by the "family physician" as common bleeding used to be.

This misrepresentation of the danger of tracheotomy has caused its abandonment several times in its history. After its proving successful in the hands of Asclepiades, 100 B.C., from its being scorned and being spoken of as a crime by Cælius Aurelanius, it was lost sight of for more than two hundred years, when it was revived by Antyllus about 340 A.D. After this the writings of Rhazes, Avicenna, and others caused its suspension until the time of Paulis Ægenæta in the seventh century, who seems to have repeatedly opened the windpipe. From that date until the attempted reintroduction by Guieto de Cauliaco, in the fourteenth century, we hear nothing of the operation. Brasavola, in the middle of the sixteenth century,[2] asserts in his "Commentaries" that he himself opened the trachea in a case of a patient laboring under quinsy, and on the point of death, and thus saved his life, the surgeon not daring to perform the operation. Dr. Geo. Martyn in 1730 performed a successful tracheotomy on a young lad with croup.[3]

Dr. Michaelis[4] in a letter from New York, dated 1780, advised early operation in these words: "It is unpardonable if it is not resorted to in time."

In 1807 Napoleon offered a prize for the best essay on diphtheria. The men between whom the prize was divided, and all who were gathered at the great medical concourse in Paris when it was awarded in 1808, were, with one exception, opposed to tracheotomy. Caron upheld the operation with great energy and indefatigable perseverance. So strong were his convictions, and so great his ardor, that he offered a prize of a thousand francs to the man who would cure croup with the aid of this operation. But the opinion of the judges and the writers of the prize essays so influenced men that there was no advance made in tracheotomy until Bretonneau. It was given to Bretonneau to restore a supreme resource so unjustly condemned. Four consecutive reverses did not discourage him, and in 1825 he had the happiness of saving the daughter of his best friend by the operation.

In 1814 Thomas Chevalier,[1] of London, made a successful tracheotomy in diphtheritic croup in a boy seven years old. Such, however, was the opposition to and dread of the operation, that[2] "in 1820 a medical gentleman of high standing in this city (Edinburgh) who was anxious to afford relief to two of his children affected by croup could not prevail upon any of the principal surgeons to perform tracheotomy. At his urgent request Dr. Bryce, a gentleman in general practice, operated on one of the children without ultimate success, as both of them died."

Though we need not apprehend the abandonment of the operation to-day, an exaggeration of its dangers might be the means of its being withheld from many who could be saved by it, or of its not being resorted to until it is too late to accomplish any good. Let not the erroneous and dangerous opinion go forth from this Academy that tracheotomy is the most dangerous of all surgical operations! The diffusion of this dictum emanating from such a representative body of medical men, will be the means of destroying far more lives in a comparatively short period, than the operation itself or anything directly connected with its performance has from the time that it was first instituted, more than two thousand years ago.

Conclusions.—Tracheotomy of itself, performed with care, involves little if any danger to life.

Accidents during the operation generally result from want of care.

It prevents asphyxia, and thus gives more time for the administration of remedies, and for the system ultimately to throw off the disease.

It prevents laborious and rapid breathing and lessens exhaustion.

It allows a free supply of air, and thus assists in the cure of the original malady.

It is the supreme resource, and as the patient cannot be made worse by it, do not postpone it until there is but a forlorn hope even from it.

Persistence of the original disease, delay in the performance of the operation, and neglect after, are the causes of its failure.

Operate early, very slowly, deliberately, carefully, and without hurry.

It is never too late to operate: even though the child has stopped breathing, if life is not extinct, open the windpipe and perform artificial respiration—many children have been saved under just such conditions.

If strangulation is the main symptom neither age, constitutional condition, nor complications can furnish a contra-indication to its performance.

It alleviates suffering.

It mitigates all the symptoms.

It obviates secondary complications.

It never adds one element of danger to the original disease.

Statistics taken collectively show that nine-tenths of the cases which render the operation needful will suffocate without it.

Performed early it snatches from certain death fully two-fifths of all the cases.

No patient that dies after the operation would have lived if it had not been performed.

When it fails to save life the relief afforded and the substitution for the most agonizing mode of death—strangula-

tion—one of the least, by asthenia, are sufficient reasons to justify its performance.

The dictates of science, facts, and common humanity, unite in demanding it.

Severinus must have been inspired when in the seventeenth century he said of it: "It is a divine invention."

Allow me one more quotation, gentlemen. In THE MEDICAL RECORD of June 28, 1884, Professor Letamendi says: "In the days of more knowledge and less nonsense, tracheotomy will be ranked among the minor surgical operations."

[1] Child lived seven weeks after the operation. On autopsy lungs were found to be perfectly healthy.

[2] Communication to Med. Chirurg. Society, Edinburgh. Professor Syme thought that the operation would not do any good in this case, but yielded to Bell, the house-surgeon, who did the tracheotomy, which was followed by instant relief to the child.

[3] Respiration stopped and artificial respiration was performed for ten minutes, and had to be resorted to three times within the first hour.

[4] This is the youngest successful case operated upon in this country. This operation was performed between the tenth and eleventh month. Child is still living.

[5] Operation same year as reported.

[1] Child had double pneumonia and recovered.

[2] One case died on eighty-first day of exhaustion from diarrhœa.

COCAINE IN INTRA-NASAL SURGERY.

By WILLIAM CHAPMAN JARVIS, M.D.,

LECTURER ON LARYNGOLOGY IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE.

On the receipt of the intelligence of Koller's experiments[1] with cocaine, through Dr. Noyes' communication to THE MEDICAL RECORD, the first thought was naturally one suggestive of startling possibilities corresponding in direction with the reader's line of inquiry. In response to this impulse I have conducted a series of experiments with the new anæsthetic in operations upon the nares, and in view of the remarkable and positive character of the results obtained feel encouraged to relate my experience, with certain additional corroborative testimony.

My first experiments, conducted several weeks since with a two per cent. solution of the salt, were not extended on account of the unfavorable impression received. Though sceptical regarding the action of this solution for my purposes, I was nevertheless inclined to expect better results from a stronger preparation. A four per cent. solution of the crystalline hydrochlorate of cocaine was afterward obtained from a different source. My method of applying the salt consisted in placing pledgets of absorbent cotton in contact with the structures requiring removal, and projecting upon them, by means of a glass tube, from five to ten drops of the cocaine fluid. The cotton once moistened can be used several times at a single sitting; indeed cotton saturated with the fluid and afterward dried will remain cocainized for many hours. I employ an exceedingly fine home-made spray to produce more extensive effects.

The cases reported have been selected on account of the exaggerated sensibility of the structures involved, and as such offer excellent evidence of the powerful analgesic action of cocaine.

Mr. ——, banker, consulted me on account of an annoying nasal catarrh. Examination revealed, among other things, a deviated septum pressing against a congestive hypertrophy of the left antero-inferior turbinated tissues. The deviated cartilage extended as a narrow horizontal ledge to the osseous edge of the septum, and obstructed nasal respiration through the left nostril. While employing a probe to point out the site of the affection, it happened to lightly touch the septum. The patient started as if severely injured, and invariably exhibited signs of intense discomfort. When the manipulation was repeated, intense sensitiveness was exhibited, and my prospects of assistance from the patient in a deliberate operation could hardly have been less favorable. A pledget of absorbent cotton was inserted in the nostril, against the abnormal structures, and a few drops of the cocaine fluid placed upon it by means of a camel's-hair brush. At the expiration of twenty minutes the cotton was removed. The first effect observed was the retreat of the lower turbinated tissue from contact with the septum, thus affording more room for operative manipulation. This peculiar action of the cocaine has already been described by Dr. Bosworth. I tentatively nipped off a piece of the septum with my fenestrated cartilage forceps; the procedure, according to the patient's statement, was perfectly painless. Emboldened by this I commenced work in earnest, the slight amount of bleeding enabling me to continue operating uninterruptedly for five minutes. During this interval the patient declared there was an entire absence of sensation. The parts were then cleansed of tissue débris. In five minutes sensation had returned. I reapplied the cocainized cotton, and after leaving it in five minutes, proceeded with the operation. In this interval I removed the whole length of the remaining deviated cartilage. The patient could with difficulty find words to express his profound sense of satisfaction.

Amanda D——, aged sixteen, referred to me by Dr. S. Hemingway. Congenital occlusion of the nares from malformation of nasal and turbinated bones. Bridge of the nose almost entirely wanting. Interocular space very broad, falling of the lower jaws, with associated signs of habitual mouth-breathing. Both nostrils impacted with flesh-like masses, having almost the firmness and elasticity of rubber. The structures were jammed so tightly against the wall of the septum as to give at first sight the impression of its fusion with the cartilage. The turbinated tissues present none of the usual signs of hypertrophied membrane, having the appearance of slightly congested turbinated tissues, and having only a trifling tendency to retract when touched with cocaine. The tissues still possessed a sensibility evidently equalling that of the normal erectile structures. The posterior nares were obstructed. A case of congenital stenosis successfully treated by me several years since presented many features in common with this one.[1]

I had operated upon Amanda D—— on a previous occasion, employing my transfixion needle and écraseur. The child did not possess a particle of fortitude, causing me a great deal of trouble by her persistent crying, and in spite of every precaution for her comfort she proved herself to be one of the most intractable patients I ever had to contend with. This state of hyperæsthesia was probably due to the prolonged contact of these delicate tissues with the septum narium. The case seemed an excellent one for the employment of cocaine. I therefore placed a pledget of absorbent cotton in the left nares, and moistened it with a few drops of the solution, carried into the nostril upon a camel's-hair brush. After the expiration of fifteen minutes I removed the cotton, and deliberately transfixed the pale tissues, the passage of the needle, as stated by the patient, causing absolutely no pain. The loop was likewise painlessly introduced, and the operation satisfactorily completed.

After an interval of five days I continued operating, replenishing my cocaine bottle from a neighboring druggist. The solution, though applied as in the first instance, did not have the desired effect. I then procured a fresh solution from still another druggist. This fluid likewise failed. Later in the day I procured some of the original preparation, and found it as effective as in the first instance. Small portions of the turbinated bodies were successfully removed by means of the fenestrated cartilage forceps, an expeditious but more painful and bloody method than excision with the wire, and therefore never employed by me for this purpose. The controlling influence of the cocaine over the blood supply removed this objectionable feature, and furnished a clear field for operation. As the incisions gradually included the deeper-lying tissues they became sensitive, requiring fresh applications of the cocainized cotton.

Mr. P——, merchant, thirty-two years of age, was seen by me in consultation with Dr. Bellows, of Brooklyn. The patient had been unable to breathe through the nose for fourteen months. The nostrils closed gradually, the right being the first to become involved.

Dr. Bellows informed me that he had already been in the hands of a physician, who employed the galvano-cautery for several weeks. A surgical procedure of a more formidable character was next employed, the patient emerging from etherization only to be confined to the house for three weeks on account of the severity of the operation, and an otitis media acuta set up by the traumatism. After recovering from these unfortunate sequelæ his condition was worse than before the operation. An examination showed the right nostril to be entirely occluded by a combined deviation of the septum and turbinated hypertrophy. A very narrow chink in the left nostril permitted the occasional entrance of a feeble current of air, enabling the patient to partially remove pent-up nasal secretions. It possessed, however, very little respiratory value.

I have been gradually clearing the nostrils for several

[1] Wiener Medizinische Wochenschrift, No. 44, 1884.

[1] Archives of Laryngology, vol. iii., 1882.

weeks, removing small portions of the tissues in such way as not to interfere with the patient's business. Although the careful excision of small portions of bone and cartilage greatly diminished his suffering, there were, nevertheless, moments when he complained severely of the pain inflicted by the *rongeur* and cutting forceps. I employed cocaine by placing small bits of absorbent cotton in contact with the already wounded and tender surfaces, and dropping the solution upon it by means of a pipette. In thirty minutes the pledgets were removed and a tentative test made. Although the forceps inflicted pain, superficial sensation was reduced to a degree permitting the stripping off of membranes partly divided in a previous operation. Another application of cocaine was made, the cotton being again removed after an interval of fifteen minutes. I then commenced to divide the tissues, and was told to continue the operation, as no pain was inflicted. I continued operating for three minutes, when the patient interrupted me while cutting away the deeper structures over the vomer. In this interval bone and cartilage were alike divided without causing the slightest pain. This method of alternately benumbing and cutting was continued for more than two hours and a half, the patient being in the best of spirits during the entire interval. He left the office breathing through a free opening into the posterior nares, and thoroughly convinced of the pain-relieving properties of cocaine.

The following history, reported through the courtesy of Dr. William Vanderpoel, offers additional evidence in a case in which my écraseur was recommended: Mrs. Annie M——, aged twenty-nine years and six months, pregnant, presented herself at my office, November 3d, suffering from a growth in the left nostril which protruded three-fourths of an inch, was about three-fourths of an inch in diameter, of a dark red color, firm upon pressure, and insensible to ordinary manipulation. Two months previous she had come to me, presenting a small growth in the left nostril, which had all the characteristics of an ordinary gelatinous polypus. Under ordinary circumstances I should have removed it at once; but considering the fact that she was then four months pregnant, and had previously miscarried three times, in each instance with profuse flooding, I feared the shock of an operation and ordered a spray of carbolic solution ($\frac{1}{10}$), under which treatment the growth seemed to disappear, but a month later returned.

Still fearing an operation, on November 9th I injected the tumor with a few drops of glacial acetic acid, and also gave the patient a powder, composed of tannin, to be snuffed up the nostril as best she could. On November 15th, there was little improvement, so I decided upon an operation. To lessen the pain and shock of the operation, I employed the muriate of cocaine, two per cent. solution, applied with a camel's-hair brush, to inside of the nostril, as well as the tumor would permit the insertion of the brush.

I made three applications at intervals of ten minutes, using in all 3 ss. of the solution, or about one grain of cocaine muriate. The first application was rather painful from the contact of the brush, but the subsequent caused no uneasiness. The Jarvis' snare was then applied without any discomfort, and passed well up to the root of the tumor, which seemed to have origin from the middle turbinated bone. No pain was experienced during the operation, and after an hour and a half the tumor came away, the patient not losing more than a few drops of blood during the entire operation, and no hemorrhage followed it.

In addition to the foregoing cases I have employed cocaine to remove polypi and hypertrophied turbinated tissues, and have found it useful to facilitate the practice of posterior rhinoscopy and to alleviate pain in the larynx and pharynx. I do not consider its employment urgent in the removal of polypi and turbinated hypertrophies, since these growths, especially the former, can be in most instances removed with little or no pain by means of my nasal écraseur. The time required to make the operation painless with the snare is necessary also to prevent the occurrence of annoying hemorrhage. Although cocaine at times restrains bleeding, its action in this respect is not necessarily permanent. I have observed tissues pale and bloodless when divided under the influence of cocaine, bleed profusely as soon as the effect wore off. The employment of cocaine in the nostril has been referred to in this country by Bosworth, Bettman, Ingals, Knapp, Gruening, and Claiborne.

It is curious to note that while Professor Wöhler and Dr. Niemann mention its effects upon the tongue, they claimed it possessed no action upon the eye.[1] Von Anrep (*Archives für Physiologie*, p. 56, 1880) experimented upon himself by pencilling the tongue with a weak solution of cocaine, and observed a loss of sensation. The blood-vessels were first constricted, then dilated, and eventually resumed their normal condition. It was probably this discovery that induced Fauvel and other European laryngologists to employ cocaine in examinations of the throat. Although I have only employed a four per cent. preparation of the salt, the experiments of Jelenek[2] indicate an advantage to be obtained by the employment of stronger solutions (twenty and thirty per cent. alcoholic) of the salt. The difference will probably show itself in a deeper and more rapid effect. My remarks upon cocaine analgesia would be incomplete without reference to another agent of this kind. I allude to rhigolene. Although no record of its use in intra-nasal surgery has come under my notice, rhigolene has yielded excellent results in my hands. For the present I must content myself with a brief account of the method, since a detailed description would be foreign to the subject of my paper.

This petroleum naphtha, proposed by Dr. H. J. Bigelow, of Boston, as a local anæsthetic, boils at 70° F., and, in the form of a spray, is capable of reducing the temperature 15° below zero. Rhigolene, when applied with a suitable atomizing apparatus, will effectually freeze the tissues in less than a minute.

I make use of a special contrivance for this purpose. Its action is more prompt and deeper, but of shorter duration than that of cocaine. Cartilage and mucous membrane can be deeply and freely divided without pain or hemorrhage. The rapid disappearance of the artificial congelation makes it necessary for the operator to act with promptness and energy. In cases requiring extensive operative interference, frequently repeated applications of the rhigolene spray are necessary. This, however, does not apply to the practice of écrasement. Tissues properly snared with the wire loop of my nasal écraseur can be continuously frozen and divided. I have utilized partial cocaine anæsthesia to facilitate transfixion and snaring of the turbinated tissues, rapidly completing the operation with the rhigolene spray. It is hardly necessary to add that daylight must be employed for illumination, on account of the inflammability of the naphtha fumes.

Rhigolene acts more rapidly than ether, and for this and other reasons is to be preferred.[3]

Conclusions.—1. Cocaine is useful in intra-nasal surgery, as a local anæsthetic, for the removal of deep as well as superficial tissue abnormalities.

2. Repeated applications are required for the removal of the deeper structures, the time requisite for anæsthesia always being shorter after the first effect has been obtained.

3. By promoting quiet and preventing secretion, hemorrhage, and sneezing, it facilitates the employment of cutting instruments within the nasal cavity.

4. The action of cocaine for profound anæsthesia depends upon the quality and quantity of the salt.

[2] Wiener Medizinische Wochenschrift, No. 45, 1884.
[3] Dictionnaire de Médecine, etc., Littré and Robin.

5. In rhigolene we possess a most valuable local anæsthetic for intra-nasal operations, the effects produced being more rapid and complete but of shorter duration than those of cocaine.

6. Rhigolene is advantageously employed in conjunction with cocaine.

FURTHER OBSERVATIONS ON THE USE OF COCAINE.

By H. KNAPP, M.D.,

NEW YORK.

Since my communication on cocaine and its application, Medical Record, October 25th of this year, I have used the new anæsthetic in a considerable number of cases, of which the following may be of interest even after the galaxy of cocaine papers that have appeared in the American and foreign press since October 18th.

Case I.—*Enucleation of an eyeball under anæsthesia from injecting cocaine into the post-ocular cellular tissue.*—To-day, at my clinic at the University Medical College, I presented a patient, aged twenty-five years, in whose left eye I had diagnosticated a choroidal sarcoma. I stated before the class that it would be quite an interesting experiment to inject cocaine into the orbit, behind the globe, and afterward test the sensibility of the anterior parts of the eye, supplied by the ciliary nerves. The hour, however, drawing to a close, the practical indications of the case were the only ones we had time to attend to. I instilled two drops of a four per cent. solution of Merck's hydrochlorate of cocaine into the conjunctival sac. Five minutes later another five drops were instilled, and about six minims of the same solution injected behind the globe. This was easily done and not felt at all by the patient. The eyeball had been forcibly drawn toward the nose with a pair of fixing forceps, the point of the hypodermic syringe thrust into the orbital tissue as far as the posterior pole of the globe. Five minutes later the eye was enucleated in the usual way. The patient indicated slight pain at the division of the tendons of the recti muscles. The division of the optic nerve and the dissection of the posterior segment of the globe caused almost no pain. When the eyeball was removed, I thrust the end of the forceps an inch deep into the wound of the orbital cellular tissue. The patient did not move, and said she felt nothing. The bleeding was very scant. The eyeball was opened at once, and a typical melanotic sarcoma of the choroid, the size of a cherry pit, covered by detached retina, was exhibited to the class. Ten minutes later, when the hemorrhage had completely ceased, I united the conjunctival wound with a continuous suture. By this time the sensibility had returned, and the patient screamed at every stitch, saying that this hurt her very much, whereas during the operation she had felt almost no pain.

This observation has convinced me that even the removal of the eyeball does not lie outside the field of application of the new local anæsthetic.

Case II.—*Ptosis operation after subcutaneous injection of cocaine; anæsthetic effect not very satisfactory.*—A boy aged about ten years, with double congenital ptosis, was operated on at the clinic of the University, November 25th. I injected a few drops of a four per cent. solution of cocaine under the skin of the right upper eyelid, introducing the point of the syringe 3 mm. above the edge of the lid, near the outer commissure, and advancing it horizontally nearly to the inner commissure. In withdrawing the needle, I injected the liquid. The lid swelled slightly, was suffused with blood, and in ten minutes only partially insensible. I held it compressed between a clamp, removed an elliptical piece of skin and muscle, and stitched the lower lip of the wound to the upper, passing the sutures high up through the skin. The tissue which I removed was infiltrated with blood. The patient had pain during the whole operation, not great in the centre, but quite keen at the periphery of the wound. He was restless and uneasy. I etherized him, which took about one minute, and performed the same operation on the other eye under perfect anæsthesia. The four black silk-sutures which loosely closed each wound were removed to-day, a week later, before the class. There was no trace of suppuration; primary union had taken place in both lids, though the wounds had been protected by nothing more than a clean handkerchief, and the boy had gone home to Harlem immediately after the operation. The result in both eyes is perfect.

Case III.—*Perforation of drumhead; cocaine anæsthetizes the inner wall of the drum-cavity, but not the drumhead.*—Mr. ——, aged twenty-one, a student of medicine, presented himself on October 23d at my office, with a middle-sized, clean-cut perforation in each drumhead. The drumheads, as well as the inner walls of the drum-cavity were quite sensitive to the touch of a probe. Fifteen minutes after the instillation of cocaine, the drumheads had lost nothing of their sensibility, but the inner walls of the drum-cavity were completely anæsthetic. The patient felt a bitter taste in his throat.

Case IV.—*Cocaine in cataract operations pre-eminently useful.*—Division of primary and secondary cataract is entirely without pain—a great advantage, for it removes also the reflex contraction of the globe, which favors too great a capsular opening in soft cataract, and prolapse of vitreous or of shreds of capsule in secondary cataract. The perfect rest of the eyeball is highly favorable for an exact technique.

In extraction of senile cataract under cocaine, there is only one step connected with pain, viz., the excision of the iris. This pain is commonly not great, and easily borne. The perfect insensibility of the conjunctiva and cornea insures the steadiness of the eyeball, and the correct location of puncture, counter-puncture, and track of the section. The absence of pressure makes accidents, such as falling of iris before the knife, and prolapse of vitreous, less likely to occur. Without going into details, I may say that it assists the operator in every step, but particularly in the so-called toilet of the wound, *i.e.*, its cleansing and final adjustment.

The property of cocaine to contract the blood-vessels, which is of great advantage in operating, has been suspected of having bad after-effects. Dr. G. J. Ball, in the *New York Medical Journal*, November 22, 1884, page 587, makes the following remark: "It became a question whether the new anæsthetic might not impair nutrition in certain operations in which the slightest impairment might affect the result injuriously. In two cases of cataract extraction in which cocaine was employed, the operations had been followed by sloughing of the flap. It might be well to consider whether this was more than a mere coincidence." I think it was not. Since the introduction of cocaine, fifteen successive extractions have been performed under the influence of cocaine at the New York Ophthalmic and Aural Institute. Only one operation was followed by some reaction—it was a complicated operation. The recovery was protracted, but good. The other cases were free from any disturbance both during the operation and the course of healing, and the results were good in all.

I feel sure that in this, the most important operation in ophthalmic surgery, the rate of success will be increased by the introduction of the new anæsthetic, through Dr. C. Koller.

December 2, 1884.

The Shortest Clinical Report on Record.—A correspondent from Warren, O., would like to hear from the profession on the following case: "Man—after swallowing glass of whiskey, chewed and swallowed part of the glass." Correspondent would like to know how it should have been treated.

Clinical Department.

MURIATE OF COCAINE IN DENTISTRY.

G. W. Weld, M.D., D.D.S., of New York, believes that the best method of application of muriate of cocaine in the operation of removing tartar from the teeth, in Rigg's disease, is as follows: Wash the gums with a little dilute alcohol, then apply, by means of a camel's-hair brush, a small quantity of a ten per cent. solution of the cocaine. Renew this once or twice, when in the course of five minutes it will be found that there is a marked numbness and diminution in the sensibility of the gums corresponding to the sides of the teeth on which the application was made. The following formula is recommended:

Cocainæ chloridi (Merck)..... gr. vj.
Spiritus menthæ piperitæ ..... ʒj.

An exposed nerve pulp was treated with the above solution, and partially extirpated, without causing any pain to the patient. In the preparation of an extremely sensitive tooth for filling, a *glycerite, ninety per cent.* in strength (made by dissolving Merck's crystals in glycerine) was allowed to remain in the cavity for a period of thirty minutes. On renewing the operation the patient stated that the pain was materially deadened. The same experiment was tried with the borate of cocaine (Foucar's crystals), and similar results apparently obtained, but the paste was permitted to remain in the cavity of the tooth for twenty-four hours.

Dr. C. H. Shears writes: "I have used cocaine twice in the extraction of teeth, and in each case the operation was for a single tooth. The preparation used was a two per cent. solution. In the first case the tooth was exquisitely tender and the gum inflamed, and so closely adherent to the tooth that it was necessary to incise it. After carefully drying the gum, a small camel's hair-brush was dipped into the solution, and the gum on either side of the tooth brushed across a few times. This was repeated twice at intervals of about three minutes, making three applications in all. A few minutes later the gum lancet was used, *with almost no pain at all.* The tooth was then extracted with a little less pain than it could have been without the anæsthetic. The second case was similar to the first, and the solution was applied in the same manner, with two additional applications. After cleansing the incision from blood a few drops of the solution were instilled into it, and repeated once after about three minutes. No pain attended the incision, and the tooth was extracted with considerably less pain than in the first case."

W. P. Horton, Jr., of Cleveland, O., sends us word that he inserted a few drops of the four per cent. solution into the cavity of a sensitive tooth, and that a few minutes afterward he used the dental engine without pain.

Dr. J. R. Uhler, of Baltimore, Md., says that on November 1st, he published some experiences with muriate of cocaine in general surgery. In all cases it produced more or less superficial anæsthesia, but acted better on thin mucous membranes than on the unbroken skin. Upon the rectum, when freely used, beside benumbing the parts, it produced in two cases a rigid tonic contraction of the sphincter ani, which had previously been relaxed, and contraction of the longitudinal fibres of the gut, pulling up the mucous membrane, which before had protruded. So firm was the contraction that the sphincter stood out like a ring, and the finger could with difficulty be made to enter it. For vaccination and small operations upon the skin, the following plan was tried in two cases and found satisfactory. First, a few drops of a strong solution of the drug were painted on the skin where it was intended to be cut, and after the lapse of a few moments the knife, dipped in some of the solution, was passed gently over the part, so as to denude only a few of the outer cells of the skin, but not penetrating deeply enough to cause hemorrhage or pain. Over this minute abrasion or cut, which was made to allow the drug to get nearer to the nerves, and be absorbed, some more of the solution was painted, and after a short interval the operation was proceeded with, the patients making no complaints. Where mucous membranes are hard and very thick it will act slowly or imperfectly, unless used by hypodermic injection, and anæsthesia is most plainly perceived where nerves are most thickly distributed. In a case of labor reported in the Maryland *Medical Journal*, I purposely avoided applying cocaine to the mouth of the uterus, as I feared that tetanic rigidity of the organ might be produced.

MURIATE OF COCAINE IN GENERAL SURGERY.

Dr. J. W. Stickler, of Orange, N. J., wishing to know the effect of cocaine hydrochlorate upon the skin and underlying tissues, had the following experiment tried upon himself by Dr. T. Y. Simpson: Dr. S—— injected with an ordinary hypodermic syringe, four and one-half minims of a four per cent. solution of the alkaloid under the skin of the fore-arm. After the lapse of five minutes, the point of a knife was applied to different parts of the skin, immediately over, and adjacent to, the point of puncture, with the following result: partial anæsthesia of the skin *along the line of the injection*, most marked at the point where the fluid was deposited in the tissues, that is, at the precise point where the cocaine was forced from the point of the hypodermic needle. On either side of this line, the partial anæsthesia extended about one-eighth inch. As the anæsthesia did not become more pronounced after waiting another five minutes, a second injection of five minims was made. The needle was inserted at a point just beside, and parallel with, the first, but forced deeper into the tissues (one inch). At the end of five minutes, the same superficial test was applied as in the first instance, the face being turned aside so as not to see the application of the knife. Sensation seemed about normal, except in a band of integument, nearly one inch long, and half an inch wide, the maximum superficial anæsthesia existing along the line of the opening made in the tissues by the hypodermic needle. The hyperæsthetic line bounding the anæsthetic area (referred to by Dr. Hepburn in Medical Record, November 15, 1884) I could not define in my own case, and there did not seem to be *increased* sensitiveness at *any* point within the limits of that portion of the skin slightly congested by the action of the drug. After thirteen minutes had elapsed from the time of puncture, the doctor transfixed with a surgeon's needle the anæsthetic skin, without producing the *slightest pain.* The needle being withdrawn, an incision was slowly made with a scalpel through the entire thickness of the skin and cellular tissue, producing *so little sensation of any kind* that, had my attention been otherwise engaged, I doubt if I would have known that the doctor was cutting me. This cut was made along the line of the injection, and about corresponded in extent with the length of the hypodermic needle. The wound was left open about four minutes, when a needle was slowly introduced, at a point midway between the two extremes of the cut, into the deeper tissues. Absolutely *no sensation* was experienced till the point of the needle entered the sheath of one of the extensor muscles. That the muscle was penetrated was evident from the motion given the needle when the muscle was exercised. The pain occasioned by contact of the needle with the muscular tissue was very slight. About five minutes later, sutures were introduced without pain, but produced a sense of pressure such as Dr. Wright said he felt when a needle was thrust into the skin of his forehead (Medi-

CAL RECORD, November 22, 1884). The anæsthesia remained well pronounced half an hour. Twenty minutes after the second injection, there were slight muscular tremors; other than these, there were no evidences of systemic disturbance. It is interesting to observe that when the hypodermic needle is made to traverse a direct course through the skin and cellular tissue, the hydrochlorate of cocaine does not diffuse itself equally in every direction, but follows quite definitely the channel made for it by the needle, producing anæsthesia along this line, but to a very limited extent on either side of it. In opening an abscess, or in making any straight incision, this circumstance would find a practical application. A much larger area of skin could be rendered anæsthetic by one injection, if the cellular tissue were made more permeable by moving the point of the injecting needle from side to side after its introduction.

MURIATE OF COCAINE IN OPERATIVE GYNECOLOGY—VESICO-VAGINAL FISTULA.

DR. W. H. DOUGHTY, JR., of Augusta, Ga., writes: "The peculiar interest which attaches to all reports upon the use of the hydrochlorate of cocaine leads me to report the following observations, made November 18, 1884, upon its effects during an operation for vesico-vaginal fistula.

"The fistula was a small one, barely admitting a silver probe of ordinary size. The patient having been placed in the 'knee and breast' posture, after thoroughly cleansing the vaginal surface and roughly testing its sensitiveness, two applications (two drops each) of a two per cent. solution of the hydrochlorate of cocaine were made, three minutes apart. Two minutes later the sensitiveness was decidedly lessened, but not enough for my purpose. The solution was now freely applied with a brush, and five minutes later the application was repeated. After three minutes more the anæsthesia seemed to be complete.

"The paring was made during sixteen minutes without the slightest evidence of pain, but at the expiration of this time the patient complained and the solution was again applied. In thirteen minutes more the paring was finished without pain.

"The patient having been in the 'knee and breast' posture for more than a half-hour, and being now fatigued, was placed in Sims' position and allowed to rest for a few minutes. Upon resuming the operation, the introduction of the first two sutures was attended with considerable pain; the solution was therefore again applied, and the remaining sutures, four in number, were introduced without pain.

"The apparent effect of the drug upon the hemorrhage was worthy of note. During the first sixteen minutes of the paring there was very slight oozing, but when the sensitiveness returned the loss of blood was decidedly increased; it diminished very much after the solution was reapplied.

"The sponge was not carefully used before making the application during the introduction of the sutures, and the coagula which formed were seemingly firmer than usual and rather difficult of removal by sponging.

"Drs. T. R. Wright and J. M. Hull, of this city, were present and assisted me."

MURIATE OF COCAINE IN IRIDECTOMY—INJECTION INTO THE ANTERIOR CHAMBER.

DR. EUGENE SMITH, of Detroit, Mich., writes: "Having, during the past three weeks, proved the value of the muriate of cocaine as a local anæsthetic, in strabismus by six operations, in congenital and cortical cataract by four operations, and in iridectomy by three operations, besides several minor operations on the cornea, I wish to lay before the readers of THE MEDICAL RECORD two points in its use which *seem* to render it more efficient. I apply it in the *form of spray with a hand atomizer* and get a more rapid effect, as the movements of the lids and the lachrymal secretion do not carry off the solution as quickly as when *dropped* into the conjunctival sac.

"In my first case of iridectomy with cocaine, while the cornea was insensitive, the *iris* was unaffected by the external application, and its seizure with the forceps was, as usual, quite painful. In two cases of iridectomy, both nervous females, five minutes after spraying the cornea and conjunctiva, I made the corneal incision without pain, then *injected, by means of a small lachrymal syringe, two* (2) *drops of the two per cent. solution into the anterior chamber*, and three minutes later seized the iris with the forceps, drew it out, and completed the operation without causing pain to the patient.

"*No reaction followed its intra-ocular use.*"

FAILURES WITH COCAINE.

DR. F. C. RILEY, of this city, makes a report of two cases in ophthalmic practice which demonstrate that the much lauded new remedy is not always as reliable as might be wished.

CASE I.—Granular lids with intense pannus occurring in a girl of ten years. The photophobia in this case was so marked that, upon facing the patient toward the window in an ordinarily well-lighted room, the eyeball rolled upward and inward to such a degree as to completely hide the whole corneal expanse from view, unless the superior palpebral covering was lifted.

Two drops of a two per cent. solution of Merck's cocaine was instilled, at intervals of ten minutes, for a period of half an hour, or three instillations in all, with no perceptible effect either as regarded diminution of sensibility to light or touch. Neither was there any appreciable effect produced upon the size of the pupil, nor did the drug affect the circulation so far as it was possible to observe it.

Three days subsequent to the preceding trial, I determined upon operating to relieve the pannus, and again tried the same solution, instilling four drops every five minutes for a period of three-quarters of an hour, or in all nine instillations. Careful efforts to touch the conjunctiva or cornea at any part thereof, between each instillation, failed to elicit the slightest evidence of anything even approximating a condition of anæsthesia. Feeling that a fair trial had been given the drug in this case, I proceeded to the use of ether and performed syndectomy.

CASE II.—A lad about twelve years of age, who had a perforating ulcer of the cornea about six months since, with prolapsus of iris into the perforation, etc. Cornea almost completely cloudy or pearly. To the outer and upper segment yet remained a small spot of transparent tissue, at which point I deemed it advisable to perform an iridectomy in order to free the entrapped iris, which seemed to produce a constant irritability of the eye. Vision-perception of light only. Using the same solution of cocaine as in the former case, four drops every ten minutes for forty minutes, with absolutely no effect of any kind, either to cornea or conjunctiva, led me to the opinion that the solution was not what it should be. Subsequent results with the same solution have, however, dispelled my suspicion as to the sample used, as I have since obtained all the physiological effects so far noted by other observers. The two cases recorded, however, seem to me to prove beyond the suspicion of a doubt that there are certain conditions, pathological maybe, or individual idiosyncracies, possibly both, that tend to militate against the verdict so generally expressed thus far in favor of the anæsthetic effects of the drug. It seems to me that in the use of this substance, the cases of failure to obtain the desired end should be placed before your readers as well as the brilliant results obtained by so many of us. That it has been a great blessing to many during its short career there is no doubt, and that it will continue to prevent the attendant pain of many operations in the future I am confident. Even if it gives as universal satisfaction in time to come as it has in my hands thus far, it is indeed a friend to the suffering and distressed.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 13, 1884.

THE EARLIER EMPLOYMENT OF COCAINE.

WHILE the enthusiasm for cocaine continues but slightly abated in its intensity, a brief reference to some of the results recently obtained, as compared with the earlier records of its employment, may prove interesting.

In 1859 Mantegazza ("Sulle virtù igieniche e medicinali della Coca," pp. 76, Milano) noted the soothing influence exercised by the leaves of erythroxylon coca, when brought in contact with mucous membranes. Literature, however, seems almost unanimous in conceding to Niemann (1860) the credit of being among the first to isolate cocaine and give it a certain amount of physiological individuality.

This investigator is mentioned as having observed several of the now recognized properties of cocaine; but, singular to relate, he stated it possessed no action upon the eye. The postponement of the discovery of its anæsthetic action upon the eye was probably owing to this misleading remark. Its employment in the throat, subsequent to Niemann's observation of its action upon the tongue, furnishes some grounds for such an inference. In 1877 Ch. Fauvel, of Paris (*Gazette des Hôpitaux*, page 427), is reported by Dr. Scaglia as having utilized the anæsthetic property of cocaine to afford relief in painful anginæ. Jelinek (*Wiener Medizinische Wochenschrift*, No. 46, 1884) claims to have successfully employed cocaine to relieve painful deglutition in ulcerative laryngeal phthisis.

Equally interesting are the experiments of Thomas Moréno y Maïz (1868), detailed in his monograph "Recherches cliniques et physiologiques sur l'Erythroxylum Coca et la Cocaïne," pp. 90. The acetate of cocaine was employed in his experiments. Particularly interesting are his observations upon the hypodermic employment of cocaine. He injected a solution of the acetate of cocaine into the leg of a frog, and observed after the expiration of ten minutes distinct loss of superficial sensibility over a circumscribed area; the most powerful irritants failed to provoke motion. In a quarter of an hour the sciatic nerve was laid bare, and sensation was observed to be completely abolished. The conclusion he arrived at, "Pourrait-on l'employer (cocaine) comme anesthésique local," though slowly accepted, has been remarkably well verified.

The employment of the hypodermic method for the painless removal of tumors has been recently followed by excellent results in hospital practice. A body of gentlemen, in this city, composed of willing medical students and intelligent surgeons, have been experimenting with a view to determine the hypodermic effects of cocaine when applied directly to the sensory cutaneous nerves. In twenty minutes after the introduction of fifteen minims of a four per cent. solution, all the parts supplied by the anæsthetized nerve were rendered analgesic. The constitutional effects (vertigo, nausea, etc.), were mild and transient in character. If the inferences deduced from these observations are correct, this property of cocaine to affect all the nerve-terminals when applied to a particular radical must prove of great service for the performance of many major as well as minor surgical operations.

In 1880 Von Aurep ("Archives für Physiologie") elaborated a series of experiments with cocaine, carefully conducted upon warm- and cold-blooded animals and upon himself. Prominent among the results recorded is its action on the pupil.

The value of cocaine for the relief of pain in many acute and chronic affections is now well recognized. It has been employed for this purpose in diseases of the eye, ear, throat, urethra, etc. Injected into the urethra it has converted internal urethrotomy into a painless procedure. The combined employment of cocaine and rhigolene in operations on the nose is recorded in the present issue of this journal.

On account of the high price of the imported article an attempt has been made to produce a domestic preparation of the salt. Aside from those preparations claimed as proprietary, but really consisting of an imported alkaloid combined with a domestic acid, a large proportion of the home-made cocaine has proved unreliable.

DEAD TEETH IN THE JAWS.

WE are in receipt of numerous communications on the above subject, mostly covering ground that has already been gone over, and we have not space to give the matter further attention at this time than to allude to some points in a letter on this subject from Dr. G. V. Black, a dentist of Jacksonville, Ill., who regards this as "simply a question in pathology," and objects to the term "dead teeth," since dentists hold that in death or intentional destruction of the pulp the dentine only loses its vitality; and that while "the tooth is retained in healthy connection with the alveolar process," the cementum and periosteal membrane remain "unaffected" so far as the death of the pulp is concerned. We can but regard this assertion as much too sweeping, since when the greater part of the tooth is in a pathological condition it cannot ever afterward be considered as sound unless it were known that a reparative process began after so great an injury rather than one of a destructive character. The progress of disease in these parts is pretty well understood; it consists, first, in disturbances in the cementum, which immediately overlies and is continuous with the lifeless dentine of pulpless teeth; and, second, in the inflammation of the periosteal covering of the cementum. The acute, subacute, or chronic pericementitis thus established extends itself very often until the nutrition of the cementum is seriously interfered with and destructive inflammation of portions of the cementum follows. This

is finally attended by contaminating secretions which may be absorbed after entering the tissues, or swallowed. But even more danger to the patient may arise from the nervous irritation propagated by these diseased teeth; important regions are often thus affected. Morbific influences of this kind may continue on almost indefinitely without perceptible disturbance in the tooth, and being thus unsuspected, health may be undermined before the cause is discovered. To advise that such teeth are harmless because the local irritation is scarcely perceptible is, in many cases, to bring about irreparable injury to health. While instances of harm from retention of such defective teeth are so frequently occurring in practice, and persons with dental skill are unable to realize the mischief being done, the safer course is to advise that all dead teeth be removed, at least until such time arrives when medical specialists can determine with certainty that teeth are not the seat of any trouble that can possibly injure the patient.

THE REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES ARMY.

The annual report of the Surgeon-General of the Army for 1884 has been received, and, like previous reports, touches upon subjects of general interest. Our army now consists of 20,230 white, 2,309 colored troops, and 210 Indian scouts. Among the white troops there were on the average 1,003, or 50 per 1,000, constantly sick, being a slight increase over the previous year. Of the sick, eighty per cent. were under treatment for disease, and twenty per cent. for wounds, accidents, and injuries. The total number of deaths was 250, or 12 per 1,000, a slight increase over last year, despite the fact that we had no Indian fights during 1883–84.

It is interesting to note that for the first time on record the mortality of the colored soldiers was less than that of the white, it being only 10 per 1,000. The ratio of sickness was very slightly greater among the colored troops. These latter suffered more from venereal diseases and less from intemperance than the white troops. From which it may be provisionally inferred that while the white man takes to wine, the black man prefers the woman.

Comparative statistics show that the white troops are more susceptible to malarial disease than the black, the difference being about 76 per 1,000 of mean strength in favor of the negro.

It is further stated that typhoid fever attacks the whites one-third oftener than the negroes, but that the mortality-rate from this disease is twice as great in the latter as in the former.

Typhoid fever prevailed among the troops more extensively than it has done since the war. It is gratifying to note, however, that the mortality from this disease among the white troops has fallen from twenty-one per cent. to sixteen per cent.

Regarding the Army Medical Museum, the Surgeon-General states that during the year there have been 144 accessions, making a total, June 30, 1884, of 9,114 specimens.

As to the Library, we learn that the additions during the past year include about 4,000 volumes and 5,500 pamphlets. By actual count at the end of the fiscal year the Library contained 65,738 volumes and 86,503 pamphlets.

The need of a new fire-proof building is again insisted upon.

The publication of the third and last medical volume of the "Medical and Surgical History of the War" was delayed by the untimely death of Dr. Woodward. The completion of this volume, however, has been placed in the hands of Surgeon Charles Smart, and it will probably appear soon.

One year ago there were fourteen vacancies in the grade of Assistant Surgeon; since then five officers have died or resigned. During the year, however, twenty-two candidates have been found qualified, and there are now no vacancies in the medical corps of the army.

THE LAST REPORT OF THE NATIONAL BOARD OF HEALTH.

The "Annual Report of the National Board of Health for 1883" reaches us somewhat over a year after its first presentation to Congress. The contents of the report itself in consequence are already in large measure known.

The more active work of the Board as regards quarantine and scientific investigation was suspended by action of law in June, 1883, consequently occasion is taken in the present report to review the history of the four years of the Board's existence.

We learn that in that time there were appropriated for its use $767,500, of which $639,446.19 were expended. The largest sums were employed in sustaining a floating quarantine on the Mississippi. About $36,000 was given to aid the State Board of Health of Tennessee, while sums of from three to eleven thousand dollars were given to help other localities. About $35,000 was spent in special scientific investigations.

The sum appropriated for the Board in 1882 was but $50,000, while in 1883 the annual appropriation was cut down to $10,000.

The work of the Board has consisted mainly in assisting, by advice and money, local health authorities, in establishing maritime quarantine stations, in inaugurating an interstate and immigrant inspection service, in securing the co-operation of the United States consuls, and in prosecuting certain scientific investigations. Owing to the lack of funds, the immigrant inspection service has now been discontinued, the Mississippi Valley inspection service has been transferred to the Sanitary Council of the Mississippi Valley, the maritime quarantine stations have passed to the care of the Marine Hospital service, while the scientific work has been entirely abandoned.

The Board requests that the powers originally conferred upon it be restored; meanwhile it asks that the sum of $37,700 be appropriated for actual expenses and to enable it to perform the duties required of it by the second section of the Act of March 3, 1879.

Appended to the report are several scientific communications and special reports. The articles on "Beriberi in Ceylon," on "Leprosy in Maracaibo," on "The Filaria Disease," and the reports on cholera in Japan and in China, are of especial interest.

SOME FACTS ABOUT ADULTERATED DRUGS.

Dr. Bennett F. Davenport, Food Inspector of Massachusetts, makes a brief report in *The Sanitarian* of some of the results which he has obtained in examining for adulterations in drugs under the excellent law of his State.

Under this act the last version of the United States Pharmacopœia is made the standard.

Dr. Davenport during his first year examined about three hundred samples of pharmacopœial drugs, and found that about forty per cent. did not conform to the requirements. Among the drugs examined were one hundred samples of tincture of opium. Of these four only exceeded the maximum allowable strength of 1.60 per cent. morphine according to the 1880 Revision of the United States Pharmacopœia; while eighty-two fell below the minimum allowed of 1.20 per cent., forty-three only fell below the about 0.90 per cent. morphine which, according to the Revision of 1880, was the quantity required by the Revision of 1870. Their average strength was 0.965 per cent. morphine, the extreme being 0.336 and 1.87 per cent.

It is thus shown that some samples of laudanum are nearly six times stronger than others. Dr. Davenport also concludes that there is much greater apparent than real change in the strength of laudanum made according to the 1880 Revision of the United States Pharmacopœia.

Of the simple cinchona alkaloid salts about twenty-five per cent. were found to contain an excess of the cheaper alkaloids.

About two hundred samples of powdered pharmacopœial drugs were examined microscopically, and about twenty per cent. were found to contain foreign ingredient, or rather appeared so, for it is not common now as formerly that totally foreign substances are introduced, but it is the closely allied and inferior varieties, or damaged samples and trimmings of the very same drug, that are used. Millers now, says Dr. Davenport, study structural botany, and are becoming as expert as those whose duty it is to expose their improper practices.

The excellent suggestion is made that there be organized in this country a Society of Public Analysts similar to that which has done so much good work in England.

The results, on the whole, of Dr. Davenport's examinations are not calculated to excite alarm. They show that druggists are slow in adopting the changes of the last Pharmacopœia, and that manufacturing pharmacists are inclined to make their preparations a little weaker than the standard.

THE CLINICAL DEPARTMENT OF THE RECORD.

The very large number of short clinical communications sent to us by our readers in all parts of the country has been a source both of gratification and perplexity. While conscious of their practical value it has often been impossible to give them either the space or the prominence they deserve. We have resolved, therefore, to remedy the matter in a measure by establishing a Clinical Department in which the choicest and most original articles received will be placed, and published in such a way as to call to them proper attention. The present issue of The Record contains the first instalment of these clinical notes, and we feel sure that now and hereafter they will form a most attractive and instructive feature in our pages. It is hardly necessary to say to our contributors that communications for this department should be brief, practical, and to the point, and should express some actual lesson taught by the writer's own experience. For the rest, clinical notes may cover the whole range of practical medicine, surgery, obstetrics, and therapeutics.

THE ABUSE OF SUBSCRIPTION CLUBS.

It may be charged that we are writing with a bias, nevertheless we cannot refrain from making a little protest against the abuse of subscription clubs. It is a very widespread practice among the physicians of towns and cities to club together and take a number of medical journals. This is a wise and economical plan, up to a certain extent; but every physician ought to have one or two journals as his own personal property, and the subscription club not infrequently prevents this. It is not the hasty week-to-week reading of numerous medical journals which is helpful to a doctor. He must have the volumes on his shelf to refer to in studying his cases or preparing his papers. It is an essential now in medical writing that the author know what has been said already on his subject. Still more important to the practitioner is it that he prescribe no therapeutical measure that has already been shown to be useless, and that he leave his patient with no remedy untried. To a practitioner the bound volumes of his standard medical journal are more valuable than text-books. We speak what is only the ordinary teaching of good sense, therefore, when we say that it is neither wise nor economical for a doctor to depend alone upon a weekly visitation of a few journals for his scientific culture, or to keep him really abreast of the medical progress of the day.

FURTHER DISCOVERIES IN CHOLERA, AND CONFIRMATIONS OF KOCH'S VIEWS.

We learn that Dr. Rudolph Emmerich, of Munich, who has been studying the cholera in Naples, has discovered a peculiar micro-organism in the blood and tissues of persons affected with that disease. This organism already goes by the name of the "Emmerich Bacillus." It was found in the internal organs and blood in nine autopsies, and in the blood from the arm of one living cholera patient.

Dr. E. Van Ermengen has communicated to the Microscopical Society of Belgium the results of his pathological studies of cholera. He has made eight autopsies and thirty-four examinations of stools. The comma-bacilli have been cultivated, and successfully inoculated in dogs, rabbits, and guinea-pigs. His conclusions are almost identical with those of Koch. He says:

"The pathogenic action of these products of cultivation is very likely due to a zymosis, to an unstable albuminoid compound. Corpuscles of fresh human blood placed on Ranvier's heated platinum, and brought into contact with a drop of a serum-culture, present characteristic changes wholly comparable with those described by MM. Nicati and Rietsch in their observations on the blood of choleraic cases.

"The discovery of the comma-bacillus is of the greatest importance in the diagnosis of choleriform attacks of

doubtful nature which occur at the commencement of epidemics, and for the resort to more effective prophylactic measures which this early diagnosis allows.

"The employment of bacterioscopic methods in the diagnosis of cholera does not offer any great difficulty in practice, and it would be very desirable, in view of the serious threats of an invasion of Belgium by cholera, that a sufficient number of physicians employed in the sanitary services should be initiated therein with the least possible delay."

News of the Week.

NINTH INTERNATIONAL CONGRESS.—The committee on organization has elected the following officers: *President*—Dr. Austin Flint, Sr., New York; *Vice-Presidents*—Drs. Alfred Stillé, Philadelphia; Henry I. Bowditch, Boston; R. P. Howard, Montreal; *Secretary-General*—Dr. J. S. Billings, U. S. Army; *Treasurer*—Dr. J. M. Brown, U. S. Navy; *Members of Executive Committee* (in addition to President, Secretary-General, and Treasurer)—Dr. I. Minis Hays, Philadelphia; Dr. A. Jacobi, New York; Dr. Christopher Johnston, Baltimore; and Dr. C. Busey, Washington. The meeting is to be held in Washington, D. C., in 1887. The membership will be composed of delegates from each of the regularly organized general, State, and local medical societies. The official languages will be English, French, and German. The published discussions will be in English; and the papers in the languages in which they are delivered. The work of the Congress will be divided into eighteen sections. The detail of organization is to be entrusted to the Executive Committee.

DR. LIVINGSTON S. HINKLEY, of New York City, has been appointed Medical Superintendent of the Essex County Asylum for the Insane, Newark, N. J.

IN CASE OF CHOLERA.—The Board of Estimates and Apportionment of this city has added $50,000 to the estimate for the Health Department, to be used in case of cholera. This is very well, but an additional sum ought to be given at once for the purpose of preventing the cholera's entrance.

POLITICS AND SANITATION.—There can be little doubt that the New York City Health Board is seriously crippled by bad political influences. It is an open secret now that the Board has not suppressed the manure dump nuisances because the owners of them were of too great political importance. The slums and unhealthful tenements of the city cannot be cleaned or improved in many cases because their owners possess too much power in the wards. The President of the Board of Health was appointed as the result of a "deal" between Tammany Hall and the Republican machine.

CAUTION IN THE USE OF COCAINE.—Since the paper of Dr. Knapp (vide page 656) was in type we have received the following note from that gentleman: "Will you allow me to add a word of caution to the communication on 'Cocaine' which I sent you a week ago. I injected 6 minims of a four per cent. solution into the orbit, close to the posterior segment of the eyeball. The anæsthesia in that part was complete, and the operation and recovery of the patient were without any disturbance. During the operation I noticed that the patient's face became quite pale. I omitted to mention this in my communication, as the patient did not complain. To-day, likewise, at the University College Clinic, I injected 5 minims of a three per cent. solution underneath a sebaceous tumor, the size of a small walnut, situated in the centre of the upper lid. The anæsthesia was almost complete, and the somewhat laborious operation passed satisfactorily, but during it the patient became as pale as a corpse, felt somewhat faint, asked repeatedly for drink, and was covered with cold perspiration. In about fifteen minutes this condition of distress, which was, however, in no way alarming, disappeared. Though much larger doses—Hepburn, Hall, etc.—have been hypodermically injected before general symptoms manifested themselves, I think that five or six minims of a three per cent. solution may be too much for the orbit. The orbital cellular tissue is so vascular that it resembles cavernous tissue. Liquids injected into it may enter the general circulation more readily than from other parts. In further operations I shall inject no more than one or two minims, and gradually feel my way. I beg you, dear doctor, to grant this note a place in your columns, for I would deeply regret if my previous communication should be the cause of an unpleasant accident by inducing somebody to inject too large a dose of cocaine into the orbit."

NEW YORK ACADEMY OF MEDICINE.—At the stated meeting held December 4, 1884, the following nominations were made for officers. *For President:* Drs. Samuel T. Hubbard, A. Jacobi, William T. Lusk, T. Gaillard Thomas, and C. R. Agnew. *For Vice-President:* Drs. C. C. Lee and T. Addis Emmet. *For Corresponding Secretary:* Drs. Paul F. Mundé, H. Knapp, and L. Elsberg. *For Trustee:* Drs. H. T. Hanks, A. L. Loomis, J. Williston Wright, E. Eliot, and Frank H. Hamilton. *For Member of Committee on Admissions:* Drs. William M. McLaury, Seneca D. Powell, A. S. Hunter, C. A. Leale, L. Elsberg, and J. A. Wyeth. *For Member of Committee on Medical Education:* Drs. Joseph D. Bryant, F. R. Sturgis, and Stephen Smith. *For Member of Committee on Ethics:* Drs. A. Hadden, A. S. Hunter, T. G. Thomas, T. E. Satterthwaite, and Andrew H. Smith. *For Member of Committee on Library:* Drs. E. Darwin Hudson, Jr., and George M. Lefferts.

COCAINE OINTMENT FOR PILES.—Dr. F. A. Burrall writes: "Please mention in your coca literature that the coca leaves treated with heated lard and an alkali, form an ointment resembling stramonium ointment, which seems to possess soothing properties. Applied to the tongue it leaves an impression similar to that produced by a solution of muriate of cocaine. This ointment, prepared at my request by a leading pharmacist of this city, has been used in three cases of hemorrhoids with the effect of alleviating pain. The muriate of cocaine will, I think, be found of service in such cases, and this alkaline ointment is also worthy of further trial as a local anodyne."

DR. W. B. DE GARMO has been appointed Assistant to the Chair of Orthopædic Surgery in the New York Polyclinic.

Dr. R. W. Wilcox has been appointed one of the Assistants to the Chair of Neurology at the New York Post-graduate Medical School.

The Discoverer of the Anæsthetic Powers of Cocaine.—Dr. W. Oliver Moore writes that, in a letter received last week from Dr. Koller, it appears that he not only first used it on the eye, but suggested its use on the throat to his laryngological friends in Vienna, instead of getting his idea *from them*, as has been inaccurately reported in many of the journals. Dr. Koller is second physician to the Vienna General Hospital.

Insane Asylum Reform.—Much disturbance has been excited in the Cook County Insane Asylum recently over the revelations in the past management of the institution recently brought out. The asylum, although built for only 300 patients, has been made to hold 558. It has been managed by local politicians, and the officers and attendants have been more skilled in politics than in the care of the sick. Dr. Clevinger, special pathologist, recently made specific charges against the warden, matron, and other employees. An investigation has followed. We learn, however, that the Commissioners, after a recent visit, decided that everything was in good condition, and ended their reformatory toil with a champagne supper. The trouble excites renewed interest in the subject of the prostitution of medical charities to politics. We call to it the attention of that useful but polynomial organization, the National Association for the Protection of the Insane and the Prevention of Insanity.

Insusceptibility to Vaccination.—English statistics show that about one infant in every thousand is insusceptible to vaccination.

Tracheotomy Aspirators.—One result of the sad death of Dr. Rabbette has been the invention of several forms of apparatus for sucking secretions from the tracheal wound. One of the simplest of these is made on the principle of a dry-cup with a rubber ball.

Proffered Contribution to the Edinburgh Medical School.—Mr. William McEwan has offered to give $25,000 to the Edinburgh Medical School, provided $50,000 is raised from other sources. The sum of $75,000 is needed to complete and furnish the building.

Charges against Russian Hospitals.—At a recent meeting of the St. Petersburg Health Committee, some statements were made which throw a sinister light on some of the Russian hospitals and nurses. Professor Botkin, speaking of the large death-rate in the St. Petersburg hospitals, said: "I have come to the conclusion that the patients die mostly from weakness, for, with their daily allowance of thirteen or fourteen copecks, they cannot even buy a pound of beef for broth. In addition to this, the nurses, who are very badly paid, steal the food of the patients whenever they can." Considerable surprise is also sometimes expressed in St. Petersburg society at the rapid growth of wealth among hospital authorities.

The Ingestion of Cholera Bacilli and Cholera Dejecta.—While Dr. Klein has swallowed cholera bacilli in pure cultures, Dr. Bochefontaine, chief of Vulpian's laboratory, has swallowed pills composed of a drachm of diarrhœic fluid from a cholera patient. Dr. B. was a little ill the next day, but had no choleraic symptoms whatever. We observe that attempts are made to discredit the value of the above experiments. This is unjust, however. If Dr. Klein swallowed the true bacilli without harm, while in a cholera country, he added to the cholera question some negative evidence at any rate. Dr. Bochefontaine's experiment tends to show also that some peculiar individual factor is necessary for the development of the disease.

Death of M. Fauvel.—The death of M. Fauvel, the celebrated French sanitarian, is announced.

Then and Now.—Fifty years ago there were hardly any such things as dispensaries or out-patient departments. Now in every large city a fourth of the inhabitants (if we go by reports) are annually treated for nothing. The effect has been to make the early attainment of professional skill more easy, but the early attainment of paying professional practice more difficult.

The most Powerful Antiseptics.—Studied by their power to prevent the development of micro-organisms in sterilized broth, the biniodid of mercury stands at the head of the list of antiseptics. It is three times as strong as the bichloride. A solution of a $\frac{1}{40000}$ strength renders life impossible to any form of microbe, says M. Miguel, while of bichloride the strength must be $\frac{1}{14000}$. Iodide of silver is also more powerful than the bichloride of mercury.

Board of Medical Examiners of the State of Virginia.—The Governor of Virginia, William E. Cameron, has approved of each of the nominations of the Medical Society of Virginia made during its last session. Of the thirty-two members, only one is "not regular."

Subcutaneous Vaccination.—Bourgeois, in the *Bulletin général de Thérapeutique*, recommends the subcutaneous injection of vaccine lymph in place of the endermic method. He has employed the new method with success.

A Bust of Dr. J. Marion Sims.—A bronze bust of Dr. J. Marion Sims by Dubois, of Paris, has been placed in the rooms of the Medical Library Association in Boston. It is the gift of a lady who was successfully treated by Dr. Sims.

The Rugby Game of Foot-ball.—The decision of the Athletic Committee of the Harvard College Faculty, that the game of foot-ball, as at present played, is "brutal," "demoralizing," and "extremely dangerous," is no more than should be expected. For our part, we can only repeat what we have said, that the Rugby game is fitted only for small boys and trained pugilists. It utterly fails as an athletic sport.

Meaning of the Word Pharmacology.—A correspondent writes: "Of late the word pharmacology is being used. I would like to know its meaning. Webster defines pharmacology as 'the science or knowledge of drugs, or the art of preparing medicines.' *The Lancet* of August 16, 1884, speaks of pharmacology, *or the physiological action of drugs*. Dunglison's Medical Dictionary (1874) gives no definition for the word whatever." The term pharmacology means the science of drugs and drug ac-

tion from all possible points of view. The word has lately been much used for "experimental pharmacology," or the study of the physiological action of drugs.

The United States Marine Hospital Service afforded relief to 44,751 patients during the year 1883–84, of whom 13,078 were treated in hospitals, and 31,673 at the dispensaries. The receipts from all sources were $421,348.59, and the expenditures $465,387.45.

The United States Life-Saving Service was instrumental in saving 4,237 lives last year.

Reviews and Notices.

The Visceral Neuroses; being the Gulstonian Lectures on Neuralgia of the Stomach and Allied Disorders, delivered at the Royal College of Physicians in March, 1884. By T. Clifford Allbutt, M.A., M.D., Cantab., F.R.S. 8vo, pp. 103. Philadelphia: P. Blakiston, Son & Co. 1884.

The publishers of this little volume have done a service in giving Dr. Allbutt's lectures to the American public. The writer is an original thinker and vigorous and charming writer. In his too infrequent contributions to medical literature he has shown that he touches no subject which he does not adorn. Nor has he failed in the present case. Attention is called to a class of ailments that are not sufficiently recognized and understood by the profession in general. We need not go into any analysis of these lectures, since proper reference was made to them in The Record when they first appeared. We simply commend them most heartily to American readers.

Transactions of the Louisiana State Medical Society at its Sixth Annual Session, held at Baton Rouge, La., May 21, 22, and 23, 1884.

Proceedings of the Connecticut Medical Society, 1884. Ninety-third Annual Convention, held at New Haven, May 28th and 29th. New Series, Vol. iii., No. 1. Hartford, Conn.: S. B. St. John, M.D., Secretary, Hartford.

Transactions of the Medical Society of the State of California, during the years 1883 and 1884. Sacramento: 1884.

Transactions of the Medical Society of the State of West Virginia. Session of 1884, May 21st and 22d.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Eighty-sixth Annual Session, April, 1884.

These volumes contain many excellent reports and papers. We note, however, that most, if not all of these have appeared in various medical journals, and they do not require comment here.

Correspondence.

THE VOMITING OF PREGNANCY—DILATATION OF THE CERVIX UTERI.

To the Editor of The Medical Record.

Sir: The report in your last issue of the discussion at a late meeting of the Northwestern Society has been noted as incorrect and incomplete by several of the gentlemen who took part in it. My own remarks on the treatment of the vomiting of pregnancy by dilatation of the cervix were made late in the evening, and, as they stand, are simply unintelligible.

I ask your leave to correct them and to add mention of another case in point. The report should be as follows:

Dr. Chamberlain said that he read the paper of Dr. Copeman when it first appeared, and had since employed its methods with satisfaction. He would also remind the gentleman (Dr. Wylie) of a paper by Dr. Engleman, published in the "Gynecological Transactions."

I am accustomed to regard the nausea of pregnancy as, for the most part, a neurotic phenomenon. The reflex actions arising from the uterus seem to start mostly from its cervical portion. This is the most important portion of the organ. At birth, and even up to the approach of puberty, that portion of the womb which is between the vault of the vagina and the peritoneal reflection over the bladder and the rectum, equals in volume all the rest of the uterus.

As the long bones develop upward and downward from the diaphyses, so from this centre the vaginal portion develops downward and the fundal portion develops upward. Through this area the uterine arteries and the spinal nerves enter the womb, and here, in the cervical portion, is the centre of neurotic activity. I have repeatedly dilated the cervix to bring on delivery in cases of convulsions, and have almost uniformly seen the convulsions cease as soon as the dilatation was well advanced.

Repeatedly, if not constantly, when I have dilated the cervix to suppress the vomiting of pregnancy, the proceeding has been successful. I recall the case of a lady having a small fibroma in the posterior wall, which acted like a ball-valve over the os internum. She became pregnant and suffered from a nausea so intense and persistent that she was dependent entirely upon rectal alimentation. I dilated the cervix, the vomiting ceased and did not return.

Undoubtedly there are cases, such as Dr. Harrison has cited, where a structural change may be the cause of the vomiting, and when, as Dr. Wylie has said, there is disease of the cervical mucous membrane, the treatment should be of the mucous membrane; but I am confident, nevertheless, that there is a kind of spasm at the os internum which may be remedied by the process of dilatation, and which is the cause of a great many cases of severe vomiting in pregnant women.

Rectal tenesmus is cured often by forcible dilatation of the anus, and tenesmus of the neck of the bladder is often cured by dilatation of urethral stricture.

The case in point mentioned is as follows:

About three hours after the above remarks were made I saw in consultation a case of puerperal convulsions. The woman, a multipara, was expecting confinement in about a month, but had not notified her physician until a few hours previously, and then on account of intense cephalalgia suddenly developed. There was some œdema, partial suppression of urine, which was heavily loaded with albumen, and embarrassed respiration. There was frequent grumous vomiting. There had been one severe and prolonged convulsion, and lesser spasms.

She was hardly semi-conscious, apparently not recognizing what was going on about her, and moaning continuously with the intense pain in the head.

We wished to bleed, but were not allowed to do so. Two drops of croton-oil were administered, and dilatation was begun with the fingers, and continued with Barnes' bags. In half an hour it was so far advanced that the largest bag was distended with nearly a pint of warm water. No anæsthetic was given. The convulsive movements ceased, she lay quiet, and no longer moaned. Three hours later she was naturally delivered and at last accounts was doing fairly well. I have not personally seen her since the day of delivery.

This was the third time within little more than one year that I had met the same gentleman in such a case of uræmic coma and convulsions. In all three cases the eclamptic phenomena ceased when full dilatation was secured, and did not return.

W. M. Chamberlain, M.D.

68 West Fortieth Street, December 6, 1884.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 4, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE STATISTICAL SECRETARY reported the death of Allen S. Church, M.D.

DR. JOSEPH E. WINTERS read a paper (see p. 645) with the following title :

IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS?—WHEN SHOULD THE OPERATION BE PERFORMED.

DR. J. WILLISTON WRIGHT opened the discussion, and said that he did not regard tracheotomy as an especially difficult operation. He was well aware that when undertaken, as it frequently was, in the middle of the night, perhaps in a tenement-house, by the light of a tallow candle or a dirty kerosene lamp, with such assistants as one could under those circumstances obtain, it was an operation which almost every surgeon approached with some sense of misgiving, and especially as it usually occurred in such cases in young children with a short neck and a deep trachea. These difficulties, however, were not so great but that they might all be surmounted by one who pretended to understand anything of surgery, coupled with a cool head and a steady hand.

The incision for the operation was a simple one, involving the skin and fascia chiefly. Then came the separating of the space between the muscles which were in front of the neck, and, in doing this, the operator reached a mass of connective tissue and veins which, if wounded, frequently bled profusely. If the operator at that time was impressed with the hemorrhage which was going on, and undertook to arrest it before opening the trachea, he would probably consume the remainder of the night in so doing. However, if the case was not urgent, it might be proper to arrest some of the hemorrhage, even supposing it to be simply venous. Arterial hemorrhage, if the incision was made properly, was seldom troublesome.

On the other hand, if the case was an urgent one, one demanding immediate relief, the child dying with asphyxia, his custom was to ignore this venous hemorrhage and go on into the trachea, feeling very certain that, as the author of the paper had stated, this venous hemorrhage would usually stop as soon as the knife entered the trachea, or at least as soon as the tube was introduced.

Concerning the entrance of blood into the trachea, he had usually regarded it as a matter of no special importance. On the contrary, it had seemed to him to be the very thing needed to stimulate violent expulsive efforts which rid the trachea of mucus as well as of blood.

In that sense, therefore, he did not regard tracheotomy as either an especially difficult or dangerous operation. He regarded tracheotomy in the adult as one of the simplest operations in surgery. In the young child the operation was facilitated by placing under the neck a common wine bottle wrapped in a napkin, and allowing the head to hang over it.

With regard to the isthmus of the thyroid body, in operating in urgent cases he would be inclined to cut through it with the knife; but, on the other hand, in cases where securing of time was not so much the object, he would surround the two sides of it with a ligature and divide the tissues between the ligatures, as stated by Dr. Winters. If, however, the child was practically dead when placed upon the table, he would not stop for this mode of procedure.

As to the time at which tracheotomy should be resorted to, he was of the opinion that it should be performed early—that is, as soon as severe symptoms made their appearance which were not relieved by ordinary medical measures; in that respect he agreed with the author of the paper. If the diagnosis of membranous croup, or of diphtheritic laryngitis was well made out, he believed that the sooner the patient had the opening made into the trachea the better were his chances of getting well.

The operation, in his judgment, was not in any sense the cause of death, except, possibly, it might lead to secondary affections, but not more so than a simple incision made elsewhere.

His feeling with reference to early operation was so strong that, if the diagnosis was reasonably correct and he was unable to get anyone to perform the operation on one of his own children or a near friend, he would perform tracheotomy himself. Still further, he would perform the operation upon himself under the same circumstances were he unable to get a surgeon to perform it. He had performed the operation once with an ordinary pocket-knife in a case of foreign body in the larynx.

DR. A. JACOBI thought that the discussion should not be so much upon the general subject as upon the elaborate paper of the evening. The subject had claimed the attention of almost numberless writers for the last two generations, a fact which was proved by Dr. Winters' paper, which teemed with quotations gathered for the purpose of proving that there was no danger from tracheotomy. The author of the paper had quoted from writers on both sides of the question, but had rested upon the side of those who considered that tracheotomy was not a dangerous operation, and at this point Dr. Jacobi entered a criticism, in that the author had not stated why he did not consider tracheotomy as a dangerous operation. We should know first what the dangers were and then see if they could not be overcome. Dr. Winters had searched the literature of old Europe apparently from beginning to end, but had made mention of only one American operator, namely, Professor Gross, and in that instance almost only for the purpose of showing that Professor Gross was guilty of contradictions in his own writings, so much so that it was scarcely possible to say whether Gross really regarded the operation as dangerous or simple and easily performed.

Dr. Jacobi would have been pleased to have had more extended reference made to American operators; for example, Dr. Gay, of Boston, who published an excellent paper on this subject not many months ago, and in our own midst he could recall excellent papers by Hadden and Ripley, each of which contained a vast amount of knowledge and solid experience. More than this, there were other men in other cities who had performed the operation, and had reported a large number of cases. He thought we could have learned something from the experience of these surgeons.

With regard to the dangers of tracheotomy, the principal one was that it was usually a bungling operation, and by bungling operation he meant a bloody operation, which is not infrequent in unskilful hands. The principal thing in performing the operation was to be as considerate and slow as possible, for by so doing hemorrhage could be avoided. If the tracheal cartilages which were to be cut could be *seen* distinctly the dangers from hemorrhage would be avoided. If it was not desirable to operate below the isthmus, if there was not sufficient room to perform the operation there, Bose's operation might be performed, which consisted in pulling off a part of the isthmus. Cutting through the isthmus would give rise to some hemorrhage, and to cut through it was a mistake. Nevertheless, it must be done when the case was an urgent one, and, under those circumstances, it might be forgiven; but if there are two or three minutes to spare the isthmus should not be cut.

Dr. Jacobi was not of the opinion expressed by Professor Wright, that is, to cut directly through the isthmus when it bleeds. He had seen such operations, and he had not been able to find the trachea on account of the blood, and

had lost a patient under such circumstances. He did not regard it as an indifferent matter whether blood was drawn into the trachea or not. It was true the child coughed afterward, and threw out a good deal of the blood, but would the child throw out everything? No. Even when the child was healthy it would throw out some blood as late as ten or twenty minutes after the operation, if all of it ever came up. When blood had entered the smallest bronchi it had the same influence which a small amount of viscid mucus would have in the same position. Broncho-pneumonia in children was usually a consequence of simple bronchial catarrh. In those cases the smallest bronchi were filled with mucus, and behind them the air-cells contracted, the blood-vessels in their immediate neighborhood dilated, congestion followed, and finally broncho-pneumonia developed. Therefore, if blood entered into the smallest ramifications of the bronchi, a very frequent result was broncho-pneumonia and death, and that result could be averted by avoiding hemorrhage, and hemorrhage could be prevented by taking a little time before the trachea was opened, which in the large majority of cases could be accomplished. First *see* the trachea, and then cut into it.

There was another cause of danger. From the *résumé* of the literature given by the author of the paper it seemed that a large number of the old authors were opposed to the operation, and a large number of modern authors were not opposed to it, and why? The old surgeons operated before chloroform was discovered, or were afraid to use it, and the discovery of chloroform was only about thirty years of age. Billroth published his experience in the University of Zurich twelve or fourteen years ago, in which he declared that tracheotomy was the most formidable operation which he had ever been called upon to perform. He had not used chloroform, and that it was which made the operation so serious. Dr. Jacobi was decidedly of the opinion that anæsthetics should be used, as the occurrence of death during the operation was much more rare than when they were omitted. He then referred to cases in which children had died, struggling against nurses who took them out of bed for the purpose of making a simple nasal injection, and if babies were operated upon without the aid of an anæsthetic many would be killed who would have been saved had an anæsthetic been administered. He preferred chloroform decidedly to ether, because it took too long to bring the patient under the influence of ether.

Here, then, were the principal dangers: first, in not using chloroform, and, second, from hemorrhage.

At what stage of croup should the operation be performed? The author of the paper had stated that if the diagnosis was correct we should not wait. Dr. Jacobi was of the opinion that we should not wait until we were sure that it was a case of membranous croup; for there were some cases of croup which were not membranous. He would say that whenever there was laryngeal stenosis which would positively lead to death, operate, even if the diagnosis of the presence of membrane had not been made.

Dr. Jacobi objected to dividing croup into several stages, especially with reference to the operation; for, in some cases the symptoms demanded tracheotomy immediately. He would operate when he knew that there was laryngeal stenosis, a considerable amount of recession in the supra- and infra-clavicular regions and in the region of the ensiform process, and when he knew that these symptoms had had a duration of several hours, or sometimes several days, and that dyspnœa had been increasing rapidly, particularly in the morning only; for in the evening the symptoms are as a rule aggravated; when there was cyanosis and frequent pulse, then he would operate at once by all means. Under such circumstances we should not ask whether or not there was a membrane or some other obstruction.

It was true that diagnosis should be clear to a certain extent. There must be, of course, laryngeal stenosis, or the long-drawn-in inspiration which alone justified us in assuming that the stenosis was not in the larynx alone. Pneumonia was not a contra-indication of tracheotomy.

What could be done in cases in which there was a general constitutional diphtheritic sepsis? Decidedly much could be done under those circumstances. In such cases there was a strong indication for the operation, for this reason: as soon as the windpipe was opened the fetid inhalations from the nose and throat were removed from the lungs, which was an immense advantage. A large number of children died in consequence of these fetid inhalations. While formerly constitutional diphtheria, complicating diphtheritic croup, was considered a contra-indication to tracheotomy, Dr. Jacobi was upon the opposite side, and believed that this was one of the principal indications for the performance of the operation. In other cases we might wait a little, because of the benefit which might accrue from the use of internal remedies, and he was still of the opinion expressed in his paper read in May last, that benefit could be derived from the use of mercurial preparations. In cases of membranous croup these preparations should be tried in addition to the measures which have already been in general use. Since he had resorted to the mercurial treatment he was positive that he had saved a large number of patients, and that his percentage of recoveries without tracheotomy was much larger than it had ever been before.

Of what did the children die when tracheotomy was performed? They might die of diphtheria, but they would die of diphtheritic sepsis whether the trachea was opened or not. They might die of paralysis, of nephritis, of hemorrhage, and they might die in consequence of adenitis with gangrene occurring, perhaps, in such enlarged glands, with hemorrhage from rupture of blood-vessels by the gangrenous process. Croupous pneumonia was not so infrequent, simply as a complication of diphtheria, and very probably due to the same cause.

But the principal causes of death after tracheotomy were broncho-pneumonia, or œdema of the lungs, or descending diphtheritic membranous process. Children were apt to die of broncho-pneumonia two or three days after the operation. Pulmonary œdema might occur and kill within a few hours after the operation. Within the last ten or fifteen years he had seen a large number of patients die of descending diphtheritic process. The process would descend into the trachea and bronchi sometimes to the third bifurcation. These children would die almost at a certain hour; that is, between fifty and seventy hours after the operation. But the descending process could be relieved in many cases by the introduction of oxygen into the circulation.

In saying what he had in the way of criticism he had also meant to say that he appreciated the value and importance of the paper, one which was well worthy of close attention, for the purpose not only of gathering material for criticism but also valuable information.

Dr. J. Lewis Smith said: "All who have seen much of tracheotomy are for the most part agreed as to the dangers which attend it. The younger the child the greater the danger, so that in infancy the operation is more difficult and dangerous than in childhood. I have observed two conditions which greatly enhance the dangers in opening the windpipe. One is the late performance of the operation, when the patient is nearly moribund and the operator is impelled to operate in the quickest possible time in the fear that the patient will die on the table. He does not have time to pick his way cautiously between the blood-vessels, consequently, there is greater hemorrhage, and the trachea is opened before the bleeding entirely ceases. The second condition is when the operator does not fully appreciate the difficulties in the way, and undertakes the operation when poorly prepared with instruments, and in other ways. Such a case was the first tracheotomy which I witnessed. Soon after my

graduation a young physician, full of confidence, met me in the street, and wished me to hold a child while he operated. Unfortunately the patient was an infant, with short neck and fleshy. He was restless during the cutting, and died from the abundant hemorrhage before the trachea was reached. Inexperience and the lack of proper appreciation of the difficulties attending tracheotomy therefore increased greatly the dangers of the operation. From the tenor of the paper to which we have listened, the young physician might be led to suppose that tracheotomy is a simple procedure and attended by little risk or difficulty, but I would strongly advise one who operates for the first half dozen times to have with him a physician or surgeon who is familiar with tracheotomy, for he is apt to be confronted in the operation by unexpected difficulties, as the presence and abnormal distribution of large blood-vessels. In the city such help is readily obtained, but in the country it might be more difficult.

"In considering the time when tracheotomy should be performed, it seems to me convenient to recognize two classes of cases. When croup commences in the beginning of diphtheria the inflammation is active, the exudation occurs rapidly, and a thick pseudo-membrane soon forms, causing a laryngeal stenosis which is apt to increase from hour to hour in spite of our inhalations and medicines. In such cases I think we all agree that the earlier tracheotomy is performed the better. In other instances diphtheria has continued a few days and the acute stage has passed when croup begins, the exudation is poured out less rapidly and less abundantly, the stenosis is not so urgent, and the patient not infrequently, in the type of diphtheria now prevailing, recovers by inhalations and medicinal treatment. While, therefore, in the one class of cases the rapidly increasing stenosis is such as to render recovery almost impossible without surgical interference, in the other class of cases the subacute character of the inflammation and the slowness of the exudative process give more time for the action of medicines, so that perhaps tracheotomy may be avoided. During the last few months I have seen two patients recover from marked larngeal stenosis due to croup commencing at the close of the first week, or in the second week of diphtheria. In both there was membranous exudation on the fauces, and such dyspnœa that the post-clavicular and infra-mammary regions were depressed on inspiration, but the dyspnœa was not progressive, the suffering was not marked, and time was allowed for the action of alkaline inhalations and medicinal measures, and tracheotomy was fortunately avoided.

"If, therefore, there is marked and increasing laryngeal stenosis, notwithstanding well-directed and energetic treatment, and the patient begins to suffer from lack of air, all of us, I think, would advise early tracheotomy, but in the other class of cases it is proper to wait and tracheotomy may not be necessary.

"The position taken by the writer that we must be sure of the presence of a pseudo-membrane in the larynx before deciding to operate, I agree with Dr. Jacobi, does not seem to me well taken. It is difficult to inspect the larynx with the laryngoscope when the fauces are much swollen, and the stenosis may be such as to require tracheotomy when there is no pseudo-membrane in the air-passages. Trousseau has pointed out that there may be even a faucial pseudo-membrane while the obstruction in the larynx is due to the infiltration and thickening of the mucous membrane. In at least two cases in the New York Foundling Asylum in which death occurred from croup, no pseudo-membrane was found in the air-passages, but thickening of the mucous and submucous tissues sufficient to cause fatal stenosis. The indication for tracheotomy is the amount of obstruction and dyspnœa, rather than the presence or absence of a pseudo-membrane. Those who believe that there is no remedy for croup except tracheotomy, would be likely to advise the operation in all cases, when there is marked dyspnœa, but I am sure that a considerable number may be relieved without tracheotomy by the judicious use of calomel in a few doses at the commencement, perhaps by one or two doses of the turpeth mineral to which our esteemed President called attention several years since, by the use of the bichloride of mercury, and especially by the persistent use of alkaline inhalations."

Dr. John H. Ripley had been interested in the paper of the evening, especially as the author had taken a position quite antagonistic to that which he himself occupied. Dr. Winters' position with regard to the dangers, the difficulties, and the consequences of late operation were opposed to Dr. Ripley's views. In support of his own views with regard to the dangers of the operation, Dr. Winters had marshalled a large number of ancient and modern men of foreign countries, some of whom had performed tracheotomy, and some of whom had never done so; some of whom had performed tracheotomy for croup, and some of whom for other causes; some of whom had performed the operation in children, and others who had performed it in adults. As Dr. Ripley understood the question, it was not whether the operation of tracheotomy in general was a difficult or a dangerous surgical procedure, but it was whether tracheotomy in children for croup was a difficult and dangerous operation. So far as tracheotomy generally was concerned, he should be willing to put in a demurrer to the position taken by Dr. Winters, as it was well known that it was neither very difficult nor very dangerous.

The danger in cases of croup consisted, first, in the condition of the child; second, in the necessity for performing the operation within a given length of time. Dr. Winters had considered one danger, and, so far as Dr. Ripley had been able to discover, he had touched upon only one, or at least but very little upon any other, namely, hemorrhage. Dr. Ripley did not understand that hemorrhage was the most common cause of death during the operation of tracheotomy. The operator had to deal with children who were suffering from systemic poisoning, from stenosis of the larynx, often from infiltration of the cellular tissue of the neck, which was sometimes immensely swollen. In order to reach the trachea under these circumstances the surgeon must go down for perhaps two inches, which necessitated a good deal of time and a good deal of care, and these little children were so paralyzed with the poison of diphtheria that, before the surgeon reached the trachea, the patients were liable to die from *syncope*, and not from hemorrhage.

If, when the stenosis was very great, chloroform was administered, the child was liable to die of apnœa; but if chloroform were not administered, as Dr. Jacobi has properly said, the child would die from paralysis of the heart and respiratory muscles incident to struggling.

With reference, then, to tracheotomy being a dangerous operation, he was willing to go with the small majority made up of such gentlemen as Professor Gross, Mr. Holmes, and Professor Billroth, and should feel satisfied if he maintained the position which those men had taken. He thought it was fair to presume that their opinions were based upon an extensive clinical experience.

Dr. Ripley had performed tracheotomy one hundred and ten times, and had seen it performed at least fifty times more. He had also seen nearly every form of complication which could exist, and had seen all sorts of operators make a trial of it. He had assisted several operators at their first operation, and believed that he had been the means of saving several lives by being present at operations performed by inexperienced operators. He had known a large number of deaths to occur upon the table.

He did not say, as had been indicated by the author of the paper, that tracheotomy was the most dangerous of all operations. He simply said that tracheotomy for croup in young children was one of the most dangerous operations in surgery. He also said that his opinion was

supported by Gross, Holmes, and Jacobi. He also was familiar with the opinions of most of the surgeons in this city, and knew that those who operated a great deal considered it as a general rule a very dangerous operation.

With regard to ten deaths occurring upon the table during tracheotomy, the operations were performed by seven men, and four of those were gentlemen of remarkable surgical experience, ability, and coolness. He knew of one death which occurred from puncturing the internal jugular vein, and the patient died from hemorrhage, the operation being performed by one of the best surgeons in New York City.

He also knew of quick operations, of two or three plunges; in one the plunge was into the spinal column, in another the operator plunged into the œsophagus, and in the third the plunge was into the side of the trachea, and the scalpel went completely through it. Dr. Ripley regarded such work as rather reckless surgery. He thought it was sufficiently dangerous when the tissues were carefully dissected down to the trachea, and the trachea was *seen* before it was opened. The trachea was liable to be displaced by an enlarged gland, or other condition, and he regarded it as exceedingly dangerous to endeavor to cut into the trachea by striking it with the scalpel in the median line.

As regarded early operations, Dr. Winters had advocated strongly the performance of the operation early. As Dr. Ripley had often said, the man who operated early would have the greatest success, not for the reasons which Dr. Winters had given, however, but for the reason that unnecessary operations, as a rule, were those which were performed early. He had within the last few months watched ten cases of diphtheritic croup in which it became a question whether or not tracheotomy would be required, and in all the patients had recovered without an operation. As a matter of necessity there was great danger of making a mistake in diagnosis. It was often impossible to differentiate until the cases had been watched for two or three days, but in such cases the patients almost always get well without the operation. It was true that the operation might be demanded for inflammatory stenosis of the larynx, as Dr. Jacobi had said, but those cases were very rare; they would answer very well to the picture which the author of the paper had given as diagnostic of membranous croup. Cases of catarrhal laryngitis were, as a rule, not accompanied by a great amount of difficulty in expiration, but in certain cases there would be difficulty in both inspiration and expiration, and in these cases the patient would get well without the operation. Besides, there was a certain number of cases of diphtheritic croup in which the patients would recover without either remedies or operation. Hence it was that there were so many specifics for croup, because in a certain proportion of cases of croup the patients would recover without any treatment, especially if the air of the room was kept moist with steam.

Concerning the effects of delaying the operation, he had been complimented by Dr. Winters with the statement that his argument was illogical because he had advocated a late operation, and then went on to say that he had been called to operate for croup and found the children dead when he reached the place. Dr. Ripley was unable to see anything specially illogical in the statement which he made, and thought that if the gentlemen who read his paper would follow the course that he there advocated, they would come out all right. With reference to these cases, in one instance the doctor had not seen the patient for a number of hours, and in one case for twelve hours. If Dr. Ripley had advocated anything in his paper, it was *that all such cases should be watched very closely*.

If Dr. Winters' causes of death after late operations were really such, then they must be those which he stated, such as pneumonia and extensive bronchitis. Dr. Ripley thought that if there was any fact in scientific medicine easily demonstrated, it was that stenosis of the larynx, or stenosis of any part of the respiratory organs before the air-vesicles were reached, which was not complete, gave rise, not to congestion of the lungs, but to *anæmia* of the lungs, which can be easily ascertained by physical signs. Broncho-pneumonia, as claimed by both Dr. Jacobi and Dr. Winters, was not found, but anæmia of the lungs and certain areas of collapse which had been produced by plugging up the bronchi leading to these collapsed portions of lung tissue. If that was true, then prolonged stenosis of the larynx did not give rise to congestion of the lungs, and hence delayed operations were not dangerous on account of broncho-pneumonia which might follow. Dr. Ripley then referred to an autopsy recently made by Dr. Maxwell, in a case of diphtheritic croup, in which were found membrane extending downward as far as the third bifurcation of the bronchi, with two or three large areas of collapse, and no broncho-pneumonia whatever. Dr. Ripley then stated, as he had done previously, and he now has the records of about twenty autopsies, that in not a single instance had there been found sufficient pneumonia to produce death. The most common cause of death, whether in the early or late stage, was *bronchial croup*. Trace the bronchi out and it would be found that the membrane extended sometimes as far as the fourth or fifth bifurcation, but before the membrane lined the tubes throughout the child must die of suffocation.

There were also other causes of death, such as nephritis, which killed in quite a number of cases; also respiratory or cardiac paralysis, or both. These were the three principal causes of death after tracheotomy.

Carbonic acid poisoning had no tendency to increase the formation of membrane.

When the child did not have retraction of the chest-walls in respiration he did not perform tracheotomy.

In conclusion he simply wished to impress what he had stated with regard to the causes of death upon the table, namely, that hemorrhage was one of the most infrequent, and further, that he regarded it as eminently proper for an inexperienced man to call to his aid, if possible, an experienced man when the operation was performed.

Dr. Winters, in closing the discussion, remarked, with reference to Dr. Jacobi's criticism, that he had quoted many American writers as well as Professor Gross.

Regarding the entrance of blood into the trachea, there had been a great misconception concerning the performance of tracheotomy. Tracheotomy properly performed was almost bloodless. He had seen the operation performed for the first time very often, and had seen it done better than it was usually executed by specialists, for the reason that the operators usually proceeded with more care, and secondly, that the specialist was not accustomed to watching the disease day by day, was terrified by the appearance of the patient, and thought that preservation of life depended upon making an opening into the trachea quickly. Dr. Winters thought the operation should be performed by the man accustomed to sit by the bedside and watch the progress of the disease, and who therefore knows that it matters not if he complete the operation in one or twenty minutes.

How should tracheotomy be performed in order to be bloodless? After the incision through the integument was made the scalpel should be put aside and not taken up again until the trachea was laid bare. The separation of the tissues might be made with two pairs of forceps, or it could be done readily with the end of a pair of ordinary scissors. If any portion of the fascia could not be torn it could be raised on a director and divided, preferably by a pair of dull scissors, after being carefully inspected. When the operation was performed in this manner care was not required with reference to the entrance of blood into the trachea.

Dr. Jacobi had said that, when blood entered the trachea and the bronchi, it might cause bronchitis and

broncho-pneumonia. Dr. Winters regarded this as the view formerly advocated by Niemeyer in treating of bronchial hemorrhage. and thought that it had been almost entirely exploded; indeed, Niemeyer retracted it before his death. It was not possible for blood to get into the small bronchi, and produce broncho-pneumonia. If a small quantity of blood got into the trachea and was left there, the operation was not completed. The operation was incomplete until every portion of blood had been expelled from the trachea by titillation with a feather or other means.

Dr. Jacobi had also stated that the older writers were opposed to the operation of tracheotomy because it was before the discovery of chloroform, but Dr. Winters thought that the quotations which he had made were sufficient answer to that statement. Billroth had been referred to as opposing the operation, more especially because he had performed it without chloroform. On this point Dr. Winters stated that Billroth had performed the operation only twelve times so far as he had been able to find on record. Concerning chloroform, he had not supposed there was any question concerning the propriety of using it ordinarily in tracheotomy, nor did he suppose there was any marked difference of opinion as to which was preferable, chloroform or ether. Ether produced irritation and congestion of the air-passages sometimes amounting to acute inflammation.

With reference to membranous croup having stages, Dr. Winters did not use the word stages with reference to croup, except as quoted from Sanné, of Paris. He agreed with Dr. Jacobi, that these stages could not be always recognized.

Dr. Jacobi had also alluded to the use of mercury in the cure of croup. That bichloride of mercury was a germicide or an anti-fermentative in the cure of diphtheria Dr. Winters did not believe. It was not possible for bichloride of mercury to be introduced into the blood in sufficient quantity to act in either way. In the first place, it was given in small quantities frequently repeated, and it was rapidly eliminated, and if elimination was interfered with it induced one of two things, either vomiting or purging. Therefore there was not sufficient of the remedy accumulated in the blood to act as either a germicide or an anti-fermentative. Was it possible to get the germicidal effect of the remedy by its internal administration? Positively, no. It had no other action than that of a simple tonic, and its action in the cure of croup was precisely the same as that of iron, a remedy which it would never supersede. As to bichloride of mercury having any influence in producing resolution of the membranous exudate, it had no more action than any other mercurial salt.

With reference to the extension of diphtheria to the bronchi, if diphtheria extended into the trachea and bronchi it almost always did so before the performance of tracheotomy. Dr. Winters did not think that a post-mortem record could be found which would tend to show that the membranous exudation of diphtheria appeared in the trachea and bronchi *after* the performance of tracheotomy, when it did not exist previous to the operation. The extension of the disease was by its propagation downward, and in those cases in which it was found death occurred within a comparatively short period, before sufficient time had elapsed for the disease to extend there after the performance of the operation.

As regarded Dr. Smith's statement concerning the necessity of assistance to one inexperienced in the performance of tracheotomy, Dr. Winters could not feel that it was essential, and Dr. Smith himself had admitted that under certain circumstances in the country it was not necessary. What can be done in the country can be done in the city.

Tubage of the larynx dates from Hippocrates, although Dr. Winters was not able to state that it was then applied. It had been practised in France a great deal, but it was entirely out of use, and no one in France, experienced in the treatment of membranous croup, would think, at the present time, of tubing the larynx.

Dr. Ripley had stated that many of the gentlemen whom he had quoted had never performed tracheotomy. In answer to this, Dr. Winters said he had quoted one, possibly two, gentlemen who had never performed tracheotomy, but almost all the quotations had been made from men who had performed the operation hundreds of times, and almost all of them had performed the operation in diphtheritic croup. In regard to Dr. Gross, his book, at least, did not show that he had ever performed tracheotomy for diphtheritic croup. Dr. Ripley apparently confounded the dangers of the *operation* with the dangers of the *disease*, and said that the conditions which render the operation needful made it dangerous. Dr. Winters said that the operation itself, performed with care, was not dangerous. Any man who was competent to practise medicine could, in a time of emergency, without a single surgical instrument, perform tracheotomy in diphtheritic croup in a young child with a short, thick, swollen neck, with absolutely no danger to the patient. Such a man generally has a knife with which he can make an incision through the integument, and with an ordinary pair of scissors he can work his way to the trachea with the loss of less than a drachm of blood. When the trachea has been clearly exposed he can open it with a penknife, and he can then hold the trachea open with two bent pins and a tape going round the neck, as one surgeon did, and saved the child's life. Any man who was prepared to undertake tracheotomy in that way was far superior to the specialist who used a large array of instruments, and with one incision laid bare the trachea.

Concerning deaths upon the table, Dr. Ripley still insisted upon that occurrence as being an indication of the danger of the operaton. When death occurred upon the operating-table it was not due to the operation, unless performed with haste and carelessness. It was always due to either carelessness or late performance of the operation. Again, Dr. Ripley said that by resorting to the operation early we should operate in cases where it was not necessary. To that point Dr. Winters had alluded in his paper, and it was there that the question of diagnosis was introduced. That was the reason why the operation should be in the hands of the general practitioner, because he was a better diagnostician in croup than the surgeon, who was not accustomed to watch the progress of the disease. A man who had watched many cases of croup could be very sure of his diagnosis.

With reference to catarrhal laryngitis, spasm, and œdema, Dr. Winters impressed the fact spoken of by Dr. Ripley, that where expiration was free there was no membrane in the larynx; but the moment you have obstruction, prolonged audible expiration, voice suppressed to a whisper, there was membrane in the larynx; nothing else would produce that symptom.

Regarding prolonged obstruction to inspiration, Dr. Ripley had said that it did not produce congestion of the lungs. That view would not bear close examination. Any one familiar with the physiology of respiration knew that as soon as interference with the inspiratory act occurred embarrassment of the pulmonary circulation followed, and with this damming back of blood upon the heart, a final result was a weakened heart-force, delayed circulation, diminished aspiration force, and passive congestion of the pulmonary vessels, and to this there was no exception in protracted stenosis of the larynx. No man could prove by autopsies upon record that it did not occur in every case of protracted croup where tracheotomy had *not* been performed. Dr. Winters had examined the records of hundreds of cases, and had found passive congestion, accumulation of mucus in the bronchi, pulmonary collapse, and when the condition had existed a little longer he had found congestion of the lungs and pulmonary œdema, all the changes which exist in a case of ordinary broncho-pneumonia. Dr. Ripley had also spoken of the analogy existing between asthma and

croup so far as the lungs were concerned. Dr. Winters said there was no analogy whatever existing between the two conditions.

Dr. L. Elsberg wished to say a word in defence of the memory of his old teacher, Professor Gross, who had taught that, although the general operation of tracheotomy was perfectly simple and not difficult to perform, there were circumstances which rendered it one of the most serious and formidable operations in surgery. It was not true, as Dr. Winters had stated, that Professor Gross had not performed the operation for diphtheritic croup. Dr. Elsberg heartily sympathized with the general drift of Dr. Winters' paper, and said that he had previously placed himself upon record with the statement that any medical man worthy of the name of physician should be able to perform tracheotomy.

Dr. Winters remarked that no one would bow lower or more reverently than he to the memory of the late Professor Gross, but he believed it to be eminently proper to criticise some of the statements which this justly distinguished author had made in his work on "Foreign Bodies in the Air-passages," and, so far as his book was concerned, there did not exist in it any evidence that Professor Gross had ever performed tracheotomy for diphtheritic croup.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 12, 1884.

R. E. Van Gieson, M.D., Vice-President, in the Chair.

Dr. R. W. Wilcox presented a specimen of

CANCER OF THE BREAST—SCIRRHOUS MAMMA—

which he removed October 16, 1884.

Mrs. W——, fifty years of age, with excellent family history, and the mother of three children, had had pain in the left side of her chest for the last three years. As the pain was increased on deep inspiration she inferred that it was due to some respiratory or rheumatic affection, and applied a plaster. When she removed this plaster she noticed a small lump, about the size of the end of her index-finger, in the left breast, below the nipple. Within the next six months she began to have stinging, itching, and drawing pains at intervals, but more especially during the few days previous to the menstrual period. During the last year retraction of the nipple has been noticed. The pain gradually increased until it became constant and severe, interrupting the sleep. Had no symptoms during lactation. Has not yet reached the menopause. Axillary glands not affected.

The report of the examination of the specimen, by Dr. H. C. Coe, is as follows:

Gross appearance.—Specimen includes the entire mamma, which is of nearly normal appearance, though the nipple is small, fixed, and slightly retracted. Below the nipple is a hard mass about the size of a hazel-nut. On section the gland is found to be overgrown by adipose tissue. In the centre of the mass, just beneath the nipple, is a firm, hard, fibrous mass, which is attached to and involves the base of the nipple. Strong bands of fibrous tissue extend from the periphery of the gland to this nodule.

Microscopic examination.—The central mass is found to be largely made up of fibrous tissue. Some sections show an entire absence of cellular elements, others are filled with scattered groups of epithelial cells, having a distinct alveolar arrangement. No signs of degenerative changes throughout the growth.

Dr. Garrish asked if any member had known a patient to live ten years after removal of a breast for scirrhus. The late Dr. Valentine Mott had made the assertion that no patient could live more than six years after removal of the breast for cancer.

Dr. Wyeth referred to one case in which the patient had lived seven years after removal of the cancerous breast. In his case there had been a number of operations.

Dr Carpenter referred to a case in which, eight years ago, he assisted in removing a tumor of the breast, which microscopical examination, made by Dr. Delafield and himself, determined to be cancer. There had been no recurrence of the disease.

Dr. George A. Dixon presented specimens of

PACHYMENINGITIS INTERNA HEMORRHAGICA, WITH CEREBRAL HEMORRHAGE,

accompanied by the following history:

J. C——, thirty-three years of age; Ireland; fireman; admitted to Charity Hospital, October 27, 1884. Family history: Negative; previous history: Patient has been a hard drinker for some years, his work has been fireman on board ship. Gives no history of any trouble up to six months ago. Then, while at Madagascar, was attacked with what he called "chills and fever." Would have a chill which was quite severe, followed by headache and fever, lasting until evening; these symptoms returned each day. He complains of some epigastric pain, and has vomited some blood. Had a small hard sore on penis three months ago, followed by an eruption. Had gonorrhœa some years ago, and has discharge now.

Present condition, October 27, 1884.—Complains of above symptoms and describes headache as burning in character and occurring over front part of head. Has a pain in his back and also in epigastric region. Appetite poor; bowels regular; has no trouble in passing urine. Walks around ward.

October 30th.—Patient is rational and seems to be doing fairly well. Physical examination reveals nothing except slight enlargement of liver.

November 3d.—To-day I saw patient for the first time, having just come on the service. Patient was asleep, was easily aroused, but was drowsy. His pupils were a very little enlarged equally. Could shut both eyes tightly, and either separately. Mouth could be well drawn to either side; tongue was protruded straight. Complained of soreness on percussion over skull; said that on October 27, 1884, he had fallen down stairs, striking on left side of head; no fracture could be detected. The grasp of the right hand was weaker than that of the left. Got out of bed and walked without difficulty, but had hemiplegic gait in right leg; stood well with feet together when his eyes were shut, also on left foot, but could not stand on right foot. The right patellar tendon reflex was exaggerated, there was no ankle clonus, and the cremasteric reflexes seemed equal on the two sides. There was slight loss of sensation over entire right side. There was no trouble with either bladder or rectum. Speech was slow and drawling; patient seemed to understand questions perfectly.

Diagnosis.—Either meningeal hemorrhage, syphilitic tumor, cerebral hemorrhage, or pachymeningitis hemorrhagica.

Treatment.—Potass. iodid., grs. x. ter. in die., to be rapidly increased. Hydrarg. biniod., gr. $\frac{1}{24}$ ter. in die.

November 5th.—Patient sleeps most of the time and is more stupid, was delirious last night; has difficulty in passing urine.

November 7th.—Has had muttering delirium constantly since last note, continually says, "My head is broken." Could not be aroused this morning, and died at 3.45 P.M., just after vomiting a quantity of yellowish fluid.

Autopsy, by Dr. Banks, house-physician, twenty-four hours after death. Heart, normal, weighs twelve and one-half ounces; liver, fatty and enlarged, sixty-nine ounces; spleen, enlarged and soft, six and one-half ounces; kidneys, normal, weigh twelve ounces; lungs, hypostatic congestion at posterior border, otherwise normal, fifty-seven ounces. On removing scalp a contused

spot was seen over left parietal bone. There was no fracture of skull. Brain was carefully removed and sent to me. The brain is well developed, there is slight flattening over left hemisphere. The inner surface of the dura mater, covering the upper surface of the left hemisphere, is covered by a false membrane, in the meshes of which are extensive hemorrhages. The measurements of this false membrane are, antero-posteriorly, six and one-half inches; laterally, two and one-half inches, and one-quarter of an inch in depth. There are punctate hemorrhages in the meshes of the pia mater underneath this area, and around are pigmentary spots. This false membrane covers the posterior aspect of the first and second frontal convolutions in front, to the corner of occipital lobe behind, and covering upper two-thirds of ascending frontal and parietal convolutions, also parietal lobe. There is a recent hemorrhage in the left hemisphere, beneath superior and inferior parietal convolutions, measuring, antero-posteriorly, one inch; laterally, one and one-fourth inch, the cavity of which would hold an English walnut. This hemorrhage is situated in the internal capsule. The arteries at the base were normal; no miliary aneurisms could be detected.

The severe pain in the head, the history of alcoholism, the fall ten days before death, and the stupor with slight paresis on right side, were points to my mind in favor of one of the four conditions I have named, with the probability that it was a meningeal hemorrhage, pachymeningitis, or possibly a syphilitic tumor occurring early in disease. Unfortunately no temperature was taken, so that cerebral hemorrhage could not be excluded when I first saw him. The points of interest are: the age of patient, the recency of the syphilitic attack, the absence of any well-marked head symptoms until three days before death, the stupor occurring then and increasing rapidly, patient becoming comatose in afternoon, and the appearance of the hæmatoma—the process having been going on for years probably. It seems to me that the cerebral hemorrhage occurred only three days before death, at the time the patient became comatose, and this apoplexy was the direct cause of death. It is very unfortunate that I could find no friends of deceased to obtain a good previous history. The hemorrhage was probably due to miliary aneurisms, although none were found, and the arteries at the base were normal, as well also the kidneys and heart.

Dr. Seguin remarked that the case was interesting on account of the slight symptoms connected with the pachymeningitis, which was in accord with what he had seen in two cases in which the symptom was mainly headache of different forms—not burning pain, but severe headache.

In the first case the patient became gradually comatose without paralytic manifestations, and the autopsy showed a thick hemorrhagic clot over both hemispheres.

In the second case the first symptom was headache, not localized, but severe pain, and then there occurred rather suddenly clonic spasms in the face and hand of one side, and also paresis of that side, after which the patient became gradually more and more comatose, and died without paralysis.

In both cases the pupils were contracted. In the second case the quantity of blood within the cranial cavity was so enormous that the hemispheres were concave at the autopsy, and when the dura was pricked the blood spurted out to a great distance; yet there was no marked paresis. There was no diagnosis in either case.

With reference to miliary aneurisms, it is necessary in searching for them to sacrifice the specimen. The brain should be placed in water and allowed to decompose, when the blood-vessels can be brushed out and the aneurisms easily detected.

Dr. Peabody remarked that the case was further interesting in the comparative youth of the patient. It was rather unusual for cerebral hemorrhage to occur at this age, if the patient had normal kidneys and heart. It had occurred to him several times to find cerebral hemorrhage in young persons, and in one case the patient was a boy nineteen years of age. In that instance, however, there was a congenital narrowing of the aorta.

With reference to pachymeningitis hemorrhagica, he had observed that the disease may exist without producing any symptoms whatever until a large hemorrhage takes place. He had frequently found the lesion of pachymeningitis hemorrhagica to the extent of the formation of numerous layers up to fully formed connective tissue, in which repeated small hemorrhages had occurred, as evidenced by numerous collections of blood pigment, and in which no symptoms whatever had been given during the life of the patient.

It had also occurred to him to find cases in which the hemorrhage had been large, and the symptoms had been very pronounced, but they were merely the symptoms of pressure upon the surface of the brain.

Dr. Van Santvoord thought the traumatism in Dr. Dixon's case should have a little more stress laid upon it than it had received. He remembered, when an interne in Bellevue Hospital, that quite a large number of cases of intoxication were admitted, presenting no symptoms except semi-stupor; but the patients finally became comatose and died without marked paresis or paralysis. At the autopsy there was found fracture at the base of the skull, but the fatal lesion seemed to be surface hemorrhage, adherent or not to the dura mater. He remembered one case in particular, that of a woman, who fell and struck her head against a hard resisting substance. At the autopsy there was found extensive pachymeningitis, with quite a recent hemorrhage under a layer of membrane on both sides of the falx. In that case it was a question whether the condition dated from the fall or whether the hemorrhage only was excited by the fall. In Dr. Dixon's specimen the pachymeningitis presented the appearance of being of recent occurrence.

Dr. Dixon said a point against the last statement made by Dr. Van Santvoord was the fact that there was a good deal of pigment around the hemorrhage, which must have been of old date, and there were several layers into which it was evident that hemorrhage had been taking place from time to time.

Dr. Seguin asked Dr. Peabody if he had been able to make sure that headache was not present in his cases.

Dr. Peabody said he was not entirely sure of the absence of headache, for the reason that the cases were all hospital cases. But he was able to say that the patients did not complain of head symptoms sufficient to attract the attention of the house staff.

Dr. Dixon remarked that in his case the man complained for some months previous to admission of only chilly feelings followed by headache, disappearing in the evening, and recurring on the following morning, and when he entered the hospital he described his headache as being of a burning character, and perhaps a little more marked over the frontal region than elsewhere.

Dr. John A. Wyeth presented

A GOITRE REMOVED BY OPERATION,

with the following history: Theresa H——, thirty-six years of age, housewife, a native of Germany, had had a goitre since she was ten years of age, but it never troubled her until three years ago, when it began to increase in size, and gave rise to difficulty in swallowing and breathing. The goitre had grown principally downward, across, and to the right, until it involved the whole anterior surface of the neck. She never had exophthalmos or palpitation of the heart. During the last three years she had had cough, which caused her much pain in the goitre and in the head. There was no family history of goitre, and the patient's previous health had been good.

On admission a large goitre was seen, extending from one side of the neck to the other, and extending behind either sterno-mastoid muscle. The narrowest part appeared in the median line, where it extended from the

lower part of the thyroid cartilage to behind the sternum. The lower border dipped down behind the clavicle and sternum. The tumor was hard, no fluctuation, and measured eight inches across, three and a half inches vertically. There was some visible pulsation of vessels over tumor. The patient's general condition was good. The patient breathed with great difficulty. The laryngoscope showed vocal cords close to median line.

October 23d.—The patient has stridulous, painful cough, and breathes with much dyspnœa.

October 26th.—Operation under ether. Took the anæsthetic badly. A crucial incision was made over the tumor, followed by careful dissection. It was found necessary to extend the incision to the left, dividing the external and anterior jugular veins and the whole of the sterno-mastoid muscle; the right sterno-mastoid muscle was only partially cut.

On the left side the internal jugular vein crossed the carotid artery to the inner side and passed high over the side of the tumor and was closely adherent to it; it was ligated above and below the tumor. The trachea was pushed abruptly to the left by the tumor. About three-fourths of an inch below the larynx, on the posterior aspect of the tumor, it was calcified and tightly adherent to the trachea. Very little blood was lost during the operation, which lasted four and one-half hours. It was then found impossible to separate the tumor from the trachea. An elastic ligature was passed about the loosened part of the tumor and the wound left open. The patient breathed badly throughout the operation, but her pulse remained good. After the operation the dyspnœa increased, and one and one-half hour later the patient died, apparently of œdema of the lungs. She was stimulated freely, and her pulse did not fail until twenty minutes before death. The tumor was removed post-mortem, and the part ligated off proved to be less than one-half. The lower and back parts were hard and cartilaginous, and contained deposits of calcific material which looked as if cysts had undergone calcific degeneration. The vessels on the right side were not disturbed, but on the left side the carotid was exposed for four inches with the pneumogastric nerve by its side uninjured. The internal jugular was ligated above and below the tumor. Nearly all the vascular connections of the tumor had been ligated.

In two other cases, already reported to the Society, Dr. Wyeth had removed the thyroid gland successfully.

Dr. Wendt asked Dr. Wyeth if in his successful cases he removed the thyroid gland completely.

Dr. Wyeth replied that the disease occupied only one-half of the thyroid body, which was removed with the isthmus up to its junction on the opposite side.

Dr. Wendt said the reason he asked was because Bruns, of Tübingen, had recently again directed attention to the fact that when the thyroid body had been completely removed the patient developed a peculiar characteristic cachectic condition, and had often died at periods varying in length from six months to several years after the operation. This observer had concluded that complete removal of the thyroid body was therefore unjustifiable, whether the gland was diseased or not.

Dr. Wyeth remarked that he did not wish to be understood as favoring removal of the thyroid body by surgical operation.

Dr. Howe thought that the application of so many ligatures could be avoided by adopting a plan recommended by Bluxom, of Charing-Cross Hospital, London, who makes an incision in the median line, divides the tumor into two equal parts, then ligates one-fourth of the tumor, tying it on each side, and cuts the mass included in that ligature completely out without special hemorrhage. He reports three cases of recovery without the development of any peculiar cachexia.

Dr. Wyeth said that in his last case the tumor was so vascular that had he split the tumor with a ligature the woman would have died of hemorrhage at once.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 30 to December 6, 1884.

Irwin, B. J. D., Major and Surgeon. Granted one month's leave of absence. S. O. 112, Department of Arizona, November 28, 1884.

O'Reilly, Robert M., Captain and Assistant Surgeon. Assigned to duty as Attending Surgeon, Washington City, D. C., to date from October 20, 1884. S. O. 284, A. G. O., December 4, 1884.

Barrows, C. C., First Lieutenant and Assistant Surgeon. In addition to other duties, to take charge of the office of Medical Director, Department of Arizona, during absence of Surgeon B. J. D. Irwin. S. O. 112, Department of Arizona, November 28, 1884.

Kneedler, William L., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort A. Lincoln, Dakota Territory, and ordered to Camp Poplar River, Montana Territory. S. O 140, Department of Dakota, November 25, 1884.

Pilcher, James E., First Lieutenant and Assistant Surgeon. To be relieved from duty at Camp Poplar River, Montana Territory, and ordered to Fort A. Lincoln, Dakota Territory. S. O. 140, Department of Dakota, November 25, 1884.

McCaw, W. D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Wingate, New Mexico, and ordered to Fort Lyon, Colorado. S. O. 228, Department of Missouri, November 26, 1884.

Gray, Charles C., Major and Surgeon. (Retired.) Died at Geneva, New York, November 26, 1884.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 6, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
November 29, 1884.....	0	42	52	2	90	55	0	0
December 6, 1884.....	0	32	67	8	155	75	0	0
Deaths.

December 6, 1884.....	0	10	13	8	22	43	0	0

A French Cure for Corns.—Saturate the stockings at the point covering the corns in a solution of phosphorus in olive oil (one part to three hundred); wear them as usual, and in fifteen or twenty days, it is claimed, the corns will have disappeared.

The Oldest Physician in the State.—Dr. Thompson Burton writes us that Dr. Joseph Braman, of Braman's Corners, Schenectady County, is the oldest Mason (and probably the oldest physician) in the State. He was ninety-one years old on August 30, 1884.

Hygiene and Bacteriology.—A department of hygiene and bacteriology has been opened in connection with the chemical laboratory of Professor Fresenius at Wiesbaden. Dr. F. Hueppe, who has done much work under Dr. Koch at Berlin, has been appointed to the charge of this department.

DO WE PRODUCE AVOIDABLE PAIN AND COMPLICATIONS IN THE DIAGNOSIS AND TREATMENT OF STRICTURE CONSECUTIVE TO GONORRHŒAL URETHRITIS?

BY FANEUIL D. WEISSE, M.D.,

PROFESSOR OF PRACTICAL AND SURGICAL ANATOMY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; VISITING SURGEON, WORKHOUSE AND ALMSHOUSE HOSPITAL, NEW YORK CITY.

THE above question is put and discussed not in the spirit of idle criticism or antagonism to orthodox practice, but with the hope that both the question and the argument may be weighed in the light of individual experience. The motive of the article is to present a strong conviction held that the present use of instruments in the urethra in the diagnosis and treatment of stricture consecutive to gonorrhœal urethritis does give needless immediate pain, and does produce avoidable local and constitutional complications. It is desired to suggest a basis for the collection of past experience and future observations, which may lead to the accumulation of positive evidence that will modify our use of instruments in the urethra in these cases. Such modification will *diminish suffering* and give more precision to our instrumental procedures for the relief of our patients.

First.—*The locality of stricture of the urethra consecutive to gonorrhœal urethritis does not warrant the introduction of instruments interiorly to the triangular ligament, or through the membranous and prostatic portions of the urethra into the bladder.*

All authorities are agreed that the prostatic portion of the urethra is never the seat of stricture from any cause. The membranous portion is acknowleged as the locality where traumatic stricture most frequently occurs. Special statistics are wanting as to the occurrence of stricture consecutive to gonorrhœal urethritis in the membranous portion.

Writers upon the subject of stricture of the urethra confirm the localization of this form of stricture exteriorly to the triangular ligament, at times by the direct statement, at others by implication, but conclusively so in the detailed recital of cases, when accurate measurements are given. Dr. Fessenden N. Otis ("Stricture of the Male Urethra," p. 134) defines stricture consecutive to gonorrhœal urethritis, as follows: "Stricture in the sense of an abnormal contraction of the urethral calibre, at some point at or between the meatus urinarius and the bulbo-membranous junction." At this "junction," it will be remembered, is the triangular ligament.

The most recent observations which have been made in locating stricture of the urethra from all causes are those of Otis and Gross; they were made upon living patients, with the metal bougie à boule.

Otis (op. cit., p. 96) located 258 strictures, from all causes, as follows: 52 in first ¼ inch within the meatus, 63 from ¼ to 1¼ inches from the meatus, 48 from 1¼ to 2¼ inches, 48 from 2¼ to 3¼ inches, 19 from 3¼ to 4¼ inches, 14 from 4¼ to 5¼ inches, 8 from 5¼ to 6¼ inches, 6 from 6¼ to 7¼ inches. The 52 cases in the first one-quarter of an inch within the meatus might be discarded as conditions of congenitally small meati.

Professor S. W. Gross, M.D. ("Diseases of the Urinary Organs," p. 454) located 173 strictures, from all causes, with the following result: 49, or 28.32 per cent., were within 2½ inches from the meatus; 48, or 27.74 per cent., were between 2½ inches from the meatus and 1 inch from the triangular ligament; 76, or 43.93 per cent., were between 1 inch in front and ¾ of an inch behind the triangular ligament.

Combining the two series of observations (less Otis' 52 cases within one-fourth of an inch of the meatus) we obtain the following localization of 379 strictures of the urethra in living patients, with *living histories:* 289, or 76.24 per cent., were between 1 inch in front of the triangular ligament and the meatus; 90, or 23.75 per cent., were between 1 inch in front of and ¾ of an inch behind the triangular ligament. If the last 90 cases had been carefully recorded as to their *locale*, so as to determine positively whether or not they were exteriorly to the triangular ligament, a very large number of them would have been located in the one inch in front of the triangular ligament. It would be safe to say that 343, *or* 90.24 *per cent., of the* 379 *strictures were located exteriorly to the triangular ligament.*

It is much to be regretted that in both Otis' and Gross' cases the causes of the strictures were not given. The weight of evidence from daily practice will fully endorse, and even go further than, Gross in his opinion (op. cit., p. 452): "Judging from my own experience, I am convinced that at least 90 per cent. of all cases, not traumatic, are the effect of gonorrhœa." Upon this basis we would not be straining a point to assume that 303, or 90.24 per cent., *of the above* 349 *strictures located exteriorly to the triangular ligament were consecutive to gonorrhœal urethritis.*

With these data in mind, and a case of suspected stricture with a history of antecedent gonorrhœal urethritis, are we warranted in passing an instrument interiorly to the triangular ligament for the diagnosis of the same? With a stricture located by instrumental examination exteriorly to the triangular ligament, why should an instrument be passed interiorly to the ligament?

I hold that all cases of stricture consecutive to gonorrhœal urethritis are located exteriorly to the triangular ligament. When the urethritis passes interiorly to the triangular ligament it may produce an epididymitis, by continuous progress into the ejaculatory ducts, etc., or an attack of cystitis by progressing to the bladder, but it does not produce stricture of the membranous portion of the urethra.

Second.—*The instruments in general use for the diagnosis and treatment of stricture of the urethra consecutive to gonorrhœal urethritis are calculated to produce needless pain and avoidable local and constitutional complications.*

The instruments in general use in the treatment of this variety of stricture are sounds and bougies; while the metal bougie à boule, urethrometers, urethral divulsors, urethral dilators, and urethrotomes are in the hands of specialists and a limited number of general practitioners.

Authors of surgical text-books, writers, as specialists, on male genito urinary diseases, professors of surgery in their didactic and clinical lectures, all concur in advising the use of sounds and bougies in the diagnosis and treatment of all cases of stricture of the urethra (making no exception for strictures consecutive to gonorrhœal urethritis). They convey the idea, if they do not say so in so many words, and practise it at their clinics, that a patient

is not examined until the sound or bougie has reached the bladder.

The history of the *armamentarium* for the diagnosis and treatment of stricture of the urethra bears evidence of a departure, here and there, from the use of the time-honored sound and bougie. They are, however, only isolated instances of a conservative appreciation of the conditions to be treated, which have not made sufficient impression upon the general profession to lead to their adoption or to any modification of the prevailing methods of practice.

After careful measurements of the sounds in general use, as made by our leading instrument makers (for their circumference Dr. C. H. Thomas' "Adaptable metric gauge" was used), the following appears:

The average length of a sound is eight and a half inches from the handle to the tip; its straight portion varies from six to seven inches, its curve from one and a half to two and a half inches; the circumference of the straight portion is uniform throughout and represents the full size of the instrument; the circumference of the curved portion diminishes from the end of the straight portion to the tip of the instrument, varying in the different instruments. In a few exceptional instances, the special make of the sound is such, that the circumference of the straight portion is continued into the curve to within an inch of the tip.

From careful measurements of flexible bougies of all kinds, French and English, they were found as follows: They vary in length from ten and one-fourth to thirteen inches; they have a uniform circumference, the full size of the bougie, to within three inches of the tip; for their terminal three inches they diminish in circumference very much, to expand again in the bulbous and olive-tipped varieties.

From the shape and length of the above instruments, as thus carefully determined, it will be seen that the curve of the one and the length of both do not adapt them for treatment of the six inches of the urethral canal exteriorly to the triangular ligament. When directed to be used it implies their passage into the bladder.

The sensations of a patient when one of these instruments is passed into the bladder are:

1. When a full-size sound or bougie is inserted, an excessively painful distention of the meatus, which is unnecessarily prolonged, because the circumference of the sound or bougie increases from the tip to the handle end of the instrument; and for six inches of the sound (straight portion) and at least nine inches of the bougie the circumference is uniform and represents the full size of the instrument.

2. Pain is always produced in passing an instrument through the triangular ligament; and a painful sense of fulness is felt while the membranous portion of the urethra is occupied by the instrument.

3. As the instrument passes through the prostatic portion of the canal over the sinus pocularis or utriculus, containing the orifices of the ejaculatory ducts, a markedly unpleasant, reflex, systemic impression is produced, which is augmented by the entrance of the instrument into the bladder.

Professor Gross (op. cit., p. 489) says: "It is well known that patients, especially such as are very nervous and irritable, occasionally suffer most violently from the most trifling operations upon the urinary organs, the mere passage of a bougie, sound, or catheter [presumably passed into the bladder][1] inducing violent rigors, excessive prostration, and other symptoms. Indeed, a large number of cases are upon record in which death was produced by this cause, even when there was no severe disease; and there are few practitioners of any experience in this branch of surgery who have not witnessed the distress, local and constitutional, which healthy persons often suffer from the attempt to pass an instrument into the bladder."

Another authority (Van Buren and Keyes, "Genito-Urinary Diseases," etc., p. 150) says: "The mischief to be feared from the employment of large sounds with force is the production of epididymitis, a common result of violence to the urethra [prostatic portion],[1] and a complication, which suspends treatment and confines the patient for several days or, it may be, weeks." Further on the same authority says: "In rare instances epididymitis may come on in spite of care."

Add to this well-known effect of the use of instruments passed into the bladder the reflection made by the last-named authorities upon epididymitis (p. 416): "One particularly interesting feature of the disease is the fact, mainly brought out of late years by Gosselin, that the chronic induration so often left behind in the epididymis by inflammation sometimes blocks up the tubes sufficiently to prevent the passage of the spermatic elements, thus entailing temporary and sometimes permanent sterility, without an accompanying loss of sexual power." Further on (p. 422) occurs the following, in speaking of this sterile condition of the patient after double epididymitis: "He ejaculates semen resembling the healthy fluid in quantity, smell, and color, only it contains no spermatozoa, and consequently he is sterile."

My own experience furnishes two cases where I examined the ejaculated fluid of patients, who had previously had attacks of epididymitis (double), where no spermatozoa could be found. In one of the cases the right epididymitis was consecutive to the gonorrhœal urethritis, while the left epididymitis was the result of the use of instruments (sounds) passed into the bladder for the treatment of a stricture consecutive to the gonorrhœal urethritis; *the stricture was located exteriorly to the triangular ligament—3¼ inches from the meatus.*

Why incur all the above risks by passing instruments interiorly to the triangular ligament when the nature of the case does not call for it?

I hold that all instruments designed to be passed into the bladder are not to be used in the diagnosis and treatment of stricture of the urethra consecutive to gonorrhœal urethritis, for the reason that I believe their passage interiorly to the triangular ligament is what produces all the above "local and constitutional distress."

For the past three years I have not passed an instrument interiorly to the triangular ligament for the diagnosis or treatment of this variety of stricture. I believe the reason that I have not had any "local and constitutional distress," from the use of instruments for diagnosis and dilatation of this form of stricture, has been because my instrumental procedures were limited to the urethral canal exteriorly to the triangular ligament.

Third.—*All instruments used in the diagnosis and treatment of stricture of the urethra consecutive to gonorrhœal urethritis should be so made as to meet the following requirements: simplicity of construction, compatible with the needs to be fulfilled; length such that they cannot be passed interiorly to the triangular ligament; a variation of circumference such as to give the least possible continuance of pain from distention of the meatus; ruled so as to locate, measure, and treat with immediate precision the stricture or strictures present.*

I would present to the profession the following perfected instruments, made for me by Stohlmann, Pfarre & Co., which have been devised to fulfil the above requirements of instruments for the diagnosis and treatment (by dilatation) of stricture of the urethra consecutive to gonorrhœal urethritis.

A set of metal bougies à boule with non-flexible, ruled staffs (Fig. 1).—These are Otis' metal bougie à boule with a non-flexible, ruled staff, and with a bulb at either end—giving two sizes to the one instrument. Its length is adapted for examination of the urethral canal exteriorly

[1] Words in brackets are added.

[1] Words in brackets added.

to the triangular ligament—it is six and one-quarter inches from the apex of one bulb to the base of the other. The *bulbs* are scaled from 14 to 37 of the French scale. The *staff*, smaller than the bulbs, has two flattened sides, which are ruled in one-quarter of an inch spaces, so that as an obstruction is met with the distance of its exterior face from the meatus can be read off. Then selecting one of the bougies, the bulb of which will go through the strictured point tightly, pass it beyond the stricture, and on attempting to withdraw the same the base of the bulb will be arrested at the interior face of the stricture, when the distance of the latter from the meatus may in turn be read off. The difference of the distances from the meatus to the exterior and interior faces of the stricture will be the length of the strictured portion.

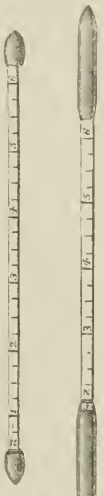

Fig. 1. Fig. 2.

A set of urethral sounds with ruled staffs (Fig. 2).—These instruments have a sound portion at either end—two sizes to one instrument—and an intervening staff portion. A *sound portion* is two inches in length; the middle, for an inch, presents the full circumference or size of the sound in millimetres (French scale); the ends (for half an inch each) taper through several sizes. The *staff portion* has much less circumference than the sound portions, and it is four and a quarter inches in length; it is flattened on two sides (one for each of the end sounds), which are ruled in inches, with the quarter-inch divisions). The length of instrument introduced into the urethra is six and one-quarter inches from the tip of one sound portion to the base of the other.

A given stricture located by the bougies à boule, the proper sized urethral sound is selected and passed, by the ruling on the staff, so as to bring the centre of the sound portion exactly at the strictured portion of the canal.

In using these instruments, the length of the urethral canal exteriorly to the triangular ligament will be found to vary from four and three-quarters to six and one-quarter inches. A little experience will enable one to recognize when the triangular ligament is reached, as it imparts to the finger, when tapping the end of the bougie à boule or urethral sound protruding from the meatus, a peculiar sensation of elasticity, not given by the exterior face of a stricture.

In closing I would suggest:

First.—That, in locating a stricture of the urethra, we determine as to whether it is exteriorly or interiorly to the triangular ligament.

Second.—That, in describing a case of stricture of the urethra, we discard all terms heretofore used in locating the same, and specifically state its relation to the triangular ligament exteriorly or interiorly. The exact distance of the same from the meatus should be stated.

Third.—That all members of the profession contribute their experience toward the accumulation of statistics, which may definitely settle the location of stricture of the urethra consecutive to gonorrhœal urethritis.

Dropping Fluids into the Eye.- The inner corner of the eye is first cleaned from all impurities, and then thoroughly dried. While the child is in the recumbent position, the eye is kept closed. One or two drops of the fluid indicated in the case are then dropped into the corner. When the child opens the lid, the drops flow slowly into the eye. Should the child be asleep, or not at once open the eye, the operator needs but slightly to separate the eyelids, when the drops will immediately enter.—*Medical and Surgical Reporter.*

ON THE NECESSITY OF PROVIDING FOR THE BETTER EDUCATION OF CHILDREN WITH DEFECTIVE HEARING IN THE PUBLIC SCHOOLS.[1]

By SAMUEL SEXTON, M.D.,

Aural Surgeon to the New York Eye and Ear Infirmary.

The purpose of this paper is to enlist an interest in our public school systems in so far as concerns the needs of pupils whose hearing disabilities prevent their advancement along with good hearing scholars, since it is believed that this matter does not receive the attention its importance demands.

The varieties of deafness.—The defective children believed to be greatly neglected in regard to their education may, for convenience in this connection, be arranged into three classes, namely:

1. Children defective in one or both ears, and requiring close proximity and distinct utterance when taught. Of these, deafness in both ears requires seating on front row of benches, but when only one ear is affected the normal ear must be toward the teacher's desk.

2. Children very deaf, who cannot distinguish ordinary conversation in either ear when more than a few inches from the speaker or unless the conversation tube, otacoustic fan, or other aid to hearing be employed.

3. The totally deaf, in whom the auditory apparatus of the middle ear cannot be made available. This class admits of division into two subdivisions, viz.: *a*, those having learned to talk previous to losing their hearing, and *b*, those born too deaf to ever have naturally acquired speech, commonly known as congenital deaf-mutes.

Deafness in the schools from a physician's point of view.—In considering the relations of all classes of deaf pupils with both the public day-schools and deaf-mute schools from the physician's point of view, it is believed that the extent and importance of the subject may be more fully realized than in any other way, since where professional advice is required opportunity is allowed for thorough examination of the hearing organs, both as regards their physical condition and acoustic functions. A very considerable experience, including observations on a large number of specially interesting cases among school children of the poorer class, seen in hospital practice, led the writer to believe that great injustice was being done in permitting children to struggle for an education under the disadvantages arising from deafness without the aid of methods which experience had shown to be advantageous in such cases; he therefore concluded to make some efforts in their behalf, and in 1877 the matter was brought to the notice of the Board of Education of New York.

Its consideration by the New York Board of Education in 1877.—The Board referred the matter to the Committee on Teachers, and in explaining the matter to them it was shown that some children continued on at school, for years even, while scarcely any hearing remained, while there were many others who heard very badly; that in disregarding this matter deaf children were placed at a serious disadvantage, and that the time wasted in futile attempts to instruct them was a hindrance to others. Instances of special injustice were cited where children, defective in hearing, had made great efforts both at school and at home to prepare themselves for promotion, only to be put back on examination, because the principal was not aware of the child's imperfection, and therefore had not given his questions distinctly enough to be heard. Other deaf children, from neglect to classify them, were seated too far away from the teacher's desk to hear his voice, and in consequence of inability to reply correctly were frequently punished for inattention and dulness. The rudeness often practised toward these un-

[1] A paper read before the Hospital Committee of the State Charities Aid Association, New York, December 3, 1884.

fortunate pupils by unthinking or unsympathetic teachers was discouraging, and some pupils in consequence had left school altogether.

It was not recommended at this time that the partially deaf should be entirely separated from the hearing pupils, yet it was advised that pupils should always be examined in regard to their hearing, and that those found to be defective should be given every possible advantage, both in respect to seating and to distinctness of voice in teaching, the very deaf should have some instruction apart from others, since they often could not understand words shouted into their ears. The writer did not expect that the long-established order of things could be rapidly changed, but it is believed that teachers have become more interested in the subject than ever before, and that instances of "inattention" and "stupidity" are less puzzling since their true character is recognized. Complaints are now less frequently made by pupils who come for treatment of neglect in this regard, and, indeed, teachers very often recommend that deaf children be brought to our clinics for relief.

Its consideration by the New York Board of Education in 1884.—During the past few months the Board of Education has again taken this matter into consideration, a communication on the subject from the writer having been referred to the Committee on "Course of Studies." The Committee met on November 12th, and on invitation the writer presented some typical cases of aural disabilities in children, and gave the results of his experience concerning deafness in the schools. The Committee have not, as yet, so far as I know, made any recommendations to the Board, but it is to be hoped that some steps will be taken in the matter soon.

Its consideration by the United States Government in 1881.—In the meantime the subject of deafness among school children has attracted the attention of the Educational Department of the United States Government, and the matter being considered important enough to justify a special investigation of its causes, the writer was requested to prepare a paper on the subject, which was printed by the Bureau of Education for distribution in 1881. An examination of five hundred and seventy-five pupils made at that time showed that there were numerous instances of deafness where neither teacher nor pupil were aware of its existence, and that fully thirteen per cent. of the whole number examined had greater or less diminished hearing in one or both ears. Of these, only three per cent. were themselves aware of any defect existing, and only one of them was known to be deaf by the teachers.

Advantages of the study of deafness from a clinical point of view.—A consideration of the subject of aural disabilities should not be confined to observations on children in the schoolroom, where the detection of deafness in many cases must be attended with difficulties, but investigations should also be made at leisure with favorable surroundings and apparatus for obtaining precise results. Hence the more valuable conclusions are to be drawn from examinations in practice, ample opportunities for which may be found in private and hospital experience. Thus from the clinical standpoint it may be premised that a large number of persons come through the ordeal of children's maladies and other ailments affecting the ears either directly or remotely with impaired hearing organs. In some the hardness of hearing is very manifest, in others it is unrecognized, even when considerable. Some apathetic persons disregard deafness, while the more sensitive endeavor to conceal their misfortune.

Estimate of the extent of aural disabilities in the United States.—Careful estimates have been made, indicating that no greater number than five per cent. of the entire population have normal hearing, but this of course does not show the number of persons defective enough to exclude them from the benefits of the ordinary common-school curriculum. The tenth census computes that there are about thirty-four thousand deaf-mutes in the United States, or 1 out of every 1,500. One half of these are illiterate.

Estimate of the extent of aural disabilities in the schools of New York City.—Nearly four thousand deaf-mutes reside in the State of New York, and over one thousand in this city. Of the latter, 575 are in asylums. The number of totally deaf persons of the school age in this city, but outside of asylums, is stated to be 163; but this estimate is much too low, since the enumeration of the census-takers is very unreliable in respect to this class. Parents are slow to acknowledge their deaf-mute progeny, and often the census-takers make no efforts to get at the facts. The writer has met with a considerable number of these children who were not enumerated, and he doubts not that there are no less than 500 of them in this city, of the school age, unprovided with educational facilities.

Before the census of 1880 was taken, the question of ascertaining the number of very deaf people was considered by the special agent, Mr. Wines, but the scheme was abandoned, as it was thought that any returns of this kind would be wholly unreliable unless obtained by the aid of expert examiners. It is, therefore, impossible to give a very close estimate of their number; but if one may form an opinion from experiences in practice, the number having more or less disqualifying aural defects may be put down at no less than ten per cent. of the entire school population of New York City. Thus out of about one hundred and forty thousand pupils in attendance at the public schools at the present time, some fourteen thousand of them would be the better for classification in respect to seating and instruction at close range, or by means of some aid to hearing. These figures show that we have to deal with a vast number of defectives, in respect to hearing, and although this avenue to illiteracy, and consequently to pauperism, was not of much significance when the country was new, it surely demands our attention now, when vagrancy and kindred evils are attracting so much attention from the vastness of their proportions.

The education of the very deaf and deaf-mutes in the day-schools.—While attention has thus been drawn to the wants of the partially deaf, strenuous efforts have been made in behalf of the deaf-mute with a view to improving his educational facilities. The labors of Professor Alexander Graham Bell in this field have been notable, and besides giving much personal attention to the work, his contributions to the literature of the subject have been numerous and valuable. But while the writer himself has mainly had in view the needs of the partially deaf, yet in pursuing this interesting subject from his own point of view, it is to be plainly seen that from a pedagogical standpoint a very considerable number of deaf-mutes, so-called, may be more advantageously provided for in the public day-schools than otherwise.

Day-schools for deaf-mutes have thus been established in the United States as follows: Horace Mann Day-school, Boston, in 1869; Erie Day school, in 1874; Chicago Day-school, in 1875; Cincinnati Day-school, in 1875; Portland, Me., Day-school, in 1876; Rhode Island Day school, in 1877; St. Louis Day-school, in 1878; Oral Branch Pennsylvania Institution, Philadelphia, in 1881; Scranton Oral School, in 1883; Phonological School, Milwaukee, in 1878; A. Graham Bell's School, Washington, D. C., 1883. It would seem that the systems of deaf-mute education were undergoing a transformation at the present time, since hearing defects are beginning to be regarded as constituting a factor of varying importance, no longer offering an insurmountable barrier, in a great number of instances, to an education which shall enable them to hold converse after the manner of hearing persons.

This leads us to express the opinion that very considerable numbers who are at present being educated as deaf-mutes could be cared for in the public day-schools

along with the very deaf who are at present unprovided for, since they both require similar methods of instruction.

Totally and very deaf children, moreover, require taking in hand at a much earlier age than is feasible in deaf and dumb institutions; their education should, in fact, begin much earlier than it is commenced at present; they should be placed in school when four or five years old. Children who have lost their hearing soon after acquiring speech soon forget to talk unless means are promptly taken to keep them in practice. The same rule would apply with equal force to the congenitally deaf, since valuable time is lost when instruction is neglected during the impressible period of early childhood. It becomes a necessity in respect to the education of children at such a tender age that they should be provided for in schools near their homes, an entirely practicable matter, fortunately, in large cities and towns, and even in sparsely populated districts, according to the reasoning of Bell in his "Memoir upon the Formation of a Deaf Variety of the Human Race."

As to disassociating very young children from home influences, the humane impulses of parents are altogether opposed to this; the writer has often witnessed the dismay and grief of parents when informed that their deaf children could obtain an education only in a deaf and dumb institution. There are, perhaps, a few families who prefer to place their children away from home, where the responsibilities of support and training will be assumed by others, but it is otherwise with our better citizens, who desire to have them brought up more as other children.

The education of the deaf in deaf-mute institutions.—In certain institutions an increased interest has shown itself of late in respect to the very considerable number of pupils who have heretofore been treated as totally deaf, but who are, in point of fact, conscious of more or less perception of sound, which may be made available in education. The results alleged to have been attained by means of aural teaching are very gratifying. During the year 1877 the writer visited some deaf-mute institutions with a view to discover what number of these pupils could hear the voice by means of a conversation-tube placed in the mouth or ear, and he was surprised to find a number being educated as deaf-mutes with whom conversation could be carried on orally by the employment of this aid to hearing. Repeated observations subsequently made by teachers have confirmed the above, and it is now believed that of all the pupils in deaf and dumb institutions a large number could be educated through the hearing sense by the aid of speaking-tubes and otacoustic fans, and that a small number hear well enough to be taught by the unaided voice. In the Minnesota institution it has been found that from fifteen to twenty-five per cent. of all the pupils received can be taught by the aural method, and that after being instructed for a time many could hear well enough at the distance of ten or fifteen feet to converse when elevated voice was used.

The confusion and consequent injustice to deaf pupils arising from neglect to classify them properly.—It will be admitted, if the figures above given concerning the deaf be approximately correct even, and it is believed that as further examinations are made they will be found not to be in excess of the correct number, that in so far as educational objects are concerned we cannot separate pupils into two great classes, *one of which can hear well and the other not at all*, by an arbitrary or sudden line of demarcation, inasmuch as the hearing disabilities of children consist in all degrees of deafness, ranging between slight defects and absolute incapacity.

It would seem necessary, therefore, that some practical scheme for the classification of the deaf should be made which would not exclude any from the schools. Under the present arrangement the only class of defectives provided for has been the so-called deaf-mute class, which leaves out of consideration entirely a large number of partially and very deaf pupils, occupying, so to speak, intermediate ground between totally deaf and normal hearing persons. This arrangement absolutely places a certain number of pupils in a worse condition than if entirely deprived of their hearing sense, and in consequence a great many of them find their way into deaf-mute schools. Thus it will be seen that the classification in both the day and deaf-mute schools is defective, and that in any attempt to improve matters we are at once met by a most perplexing dilemma; thus, owing to the long-continued practice of forcing all deaf pupils into either a totally deaf or good hearing class, we find that some of the former and all of the very deaf and partially deaf have been relegated to the hearing schools, while other very deaf persons are classified with the totally deaf and taught as deaf-mutes.

The disadvantages arising in deaf-mute institutions from the want of classification show themselves in many ways; thus, where no useful perception of sound has ever been experienced by a pupil, as in most congenitally deaf persons, there is probably an entire inaptitude for the development of the perceptive function, and while efforts to arouse this dormant function must not be too early abandoned in doubtful cases, yet it is well to consider how much labor can be profitably devoted to the task of teaching such pupils to converse orally. The discouraging results in such cases has doubtlessly been the means of establishing a preference for teaching the sign language, since in overcrowded deaf-mute institutions this method has the advantage of being inexpensive—an important item where the corps of instructors is small. It has been estimated that about ten per cent. of deaf-mute pupils belonging to this class cannot learn to speak intelligibly unless much more attention is given to their instruction than is practicable in any public school.

The mediocrity of results attained is further increased by the mental inertness of deaf-mute pupils either admitted when too old to adapt themselves successfully to study or retained too long after reaching adolescence.

The duty of the State in respect to the education of the deaf.—The opponents of the proposed reform for teaching these defectives in the public day-schools assert that the policy of the State is to exclude all who cannot be regarded as having *average* mental and physical qualifications; but no one has ventured to define this standard. Indeed, it would be difficult to do so: and were all of the *average* pupils selected, what should be done with the remaining pupils? This question has thus far been only tentatively met by the attempt to separate all pupils into good hearing and totally deaf classes.

By many it is held that our public-school system has for its principal object the prevention of illiteracy among the poor, and if this view be correct it can scarcely be regarded as consistent on the part of the advocates of educating the average child only to oppose a scheme for the promotion of the interests of a needy but uninfluential class, while fostering expensive institutions for the free education of the better-to-do, and going so far even as to expend large sums of money in giving *special* instruction in German, French, Music, etc.

This was certainly never contemplated by those who founded the common-school system. Nor is it humane to leave the care of this defective class to the uncertainties of philanthropic aid. The State already has abundant facilities for the care of all the deaf-mutes who cannot be educated in connection with the day system of public schools, and inasmuch as these institutions will soon be overcrowded by the natural increase of this class, it would seem that facilities should be provided for them in the day-schools without delay. There are, already 17,000 deaf and dumb persons of the school age in the United States, according to the census of 1880, only 5,000 of whom were in institutions. As has been stated, there are already in operation in various sections of the country eleven day-schools for the deaf, nine of

which, at least, are under control of the the local boards, and a bill is now before the Wisconsin legislature to authorize Boards of Education to take charge of deaf-mutes and place them in the day-schools.

The expense of educating the deaf in day-schools as compared with their education in institutions.—The question of reform in the education of the defective in hearing is to a certain extent a question of expense; that they must receive educational facilities will not be denied.

Let us consider the result in this regard of transferring to the day-schools what may be regarded as their legitimate share of work. The outlay by the State would probably be lessened, so far as the deaf-mutes are concerned, and, on the other hand, it would be slightly increased were proper methods introduced for the instruction of the very deaf and partially deaf.

At the present time it costs the State to support and instruct deaf-mutes in its seven asylums $250 per capita annually. It will thus be seen that were classes of ten formed in the public schools, which is a smaller number, I believe, than in asylum classes, and a teacher secured at the rate of $800 per annum, there would be a saving of $170 per pupil. Where smaller classes of children were formed, as might be done in the country, the saving would be less. I have no exact figures upon which an estimate of the number of partially deaf can be based. I know of but one extensive examination in this direction, besides my own; this was made by Weil, of Stuttgart, and published in the *Archives of Otology* for 1882. It embraced the results of an examination of the ears and the hearing of school children of different social grades. In some schools the percentage of those who heard badly was as high as 30 per cent. My own examinations, embracing 570 pupils, were made in the intermediate and primary grades and included some in the Roman Catholic Parochial and in the Colored Schools of this city. It has already been stated that about thirteen per cent. of these had greatly diminished hearing, but it would be impossible to estimate the number whose hearing required teaching by special methods without a careful and extensive examination being made. From the large number met with in practice, however, I believe the number to be considerable. These, however, could be taught in classes of twenty, and the increased expense would not be great; such pupils are at present taught, if they attend school, in classes with hearing children, and the increased expense in reducing the size of classes to accommodate them may be easily computed.

There need be no expense for new buildings, the structures at present in use for school purposes being sufficient, since it is thought best not to separate one class from another entirely any more than the different grades are now taught apart. Some instruction would be common to all.

Teachers of deaf pupils.—Many teachers have already fitted themselves for this work, and it is a significant fact that the growing demand for better instruction of the deaf has enabled them to find ready employment either in families or in conducting small private day-schools, since parents are willing to incur this extra expense rather than place their children in deaf-mute institutions. Where this expense cannot be borne, and parents are unwilling to send their children away from home, it seems that to exclude them from the advantages of day-schools is to disregard their rights.

The examination of pupils in the public schools with a view of determining their hearing power.—It will not be denied that these disabilities among pupils should be known to teachers in order that instruction may be made more successful, and it therefore becomes important to adopt some plan for correctly determining the hearing power of all school children, so that where any defect exists pupils may be placed under the best possible advantages. While teachers are known to often fail to discern marked departures from the normal standard, and children themselves cannot always give reliable information, yet much could be accomplished by principals and teachers were they assisted at the start by an expert in such matters, especially so far as the majority of pupils are concerned; but where it becomes important to ascertain the exact state of the transmitting apparatus of the ear, and the condition of the nerve-tract connected with audition, an expert examination would be required.

The importance of early training for deaf children.—Too much stress can scarcely be laid on the value of results obtainable in this way if early made, since the perceptive power may be much quickened by training in many instances, even where the middle ear apparatus is defective. It would appear to be on the development of the perceptive tract, rather than on any change in the transmitting mechanism, that mental improvement depends in the very deaf who are taught aurally. The expert himself finds it no easy task to get at the facts in certain cases, especially in young children who have already been instructed as totally deaf, since they soon come to disregard the hearing sense entirely, and it remains to be determined in such cases how much the auditory nerve has deteriorated from disuse. The professed indifference to hearing should never prevent some attempts being made at instruction through the hearing organs, since a surprising amount of hearing may thus be found to exist. How many children one meets with who are backward in learning to talk, but finally on getting to be three or four years old gain their speech! Such children would get on much faster in many instances, it is believed, if regarded as partially deaf. While treating such children professionally I have seen beneficial results from the use of conversation-tubes, or the employment of voice at close range. This practice cannot be too early commenced. I have observed good results in children as young as eighteen months. In observing these cases one cannot but be impressed with the importance of normal hearing in the ready acquirement of speech, and that however imperfect the hearing may be, it has its uses in acquiring language.

The hearing that remains after injury of the ear-drum.—Often after great impairment or destruction of the transmitting apparatus of the ear-drums, a very efficient passage of sound to the auditory nerve remains; but as this becomes more and more difficult, it deteriorates in quality, especially for long distances, until finally its rendition in the very hard-of-hearing becomes so crude and indefinite that interpretation by the perceptive tract is difficult or even impossible. Now, when sound ceases to be transmitted in this manner, hearing may take place by means of the passage of sound up through the tissues of the head to the perceptive tract as propagated by means of the otacoustic fan placed on the teeth, or the conversation-tube placed in the mouth. In the former instance sound passes more directly along bone structure from the teeth, while in the latter it ascends to the vault of the resonating chamber at the top of the pharynx and thence up through the tissues of the head. Voice-sounds imparted to a pupil in the manner just mentioned are of very great value in certain cases, because of their tones being natural, and the pupil's own voice is even more effective in this respect since it is propagated upward with much energy by his own vocal efforts against the moist and highly receptive pharyngeal vault.

The classification of the future.—No time should be lost in taking steps in this direction; a little classification must necessarily pave the way to improvement in the education of the deaf of every degree. It should be kept in mind, however, that, in a certain proportion of the partially deaf, the defectiveness is transient and variable; and that in some of the more difficult cases among the very or totally deaf, repeated examination will have to be made when any doubt as to the diagnosis remains.

Before quitting this subject I desire to mention Bell's useful device for testing the hearing.

The audiometer arranged by Professor Bell.—This instrument, for all practical purposes in testing the hear-

ing power of the different classes of deaf persons, answers almost every requirement, and its introduction will very much facilitate the work of classification when used by an intelligent and trained examiner.

CHRONIC PNEUMONIA, PHTHISIS, AND MILIARY TUBERCULOSIS IN THE LIGHT OF RECENT DISCOVERIES.

By EDMUND C. WENDT, M.D.,

CURATOR TO THE ST. FRANCIS HOSPITAL, NEW YORK.

It is the opinion of the writer that the micro-parasitic nature of genuine tuberculosis may now be accepted as proved by the convincing force of exact experimental demonstration. In this direction few will to-day attempt to dispute the correctness of Koch's well-known assertions. But practical clinical investigation must needs supplement, modify, or perhaps even disprove some of the later claims put forward by Germany's noted mycologist. In the second volume of the *Mittheilungen aus dem Reichsgesundheitsamt* Koch has recently published more extended observations, dealing principally with the etiology of tuberculosis. One highly important statement, to my mind, is to the effect that the repeated entrance into the healthy human lung of small numbers of the specific bacilli of tuberculosis results in chronic phthisis, whereas the simultaneous admission of numerous microbes produces acute miliary tuberculosis. This ingenious, significant, and far-reaching hypothesis certainly requires corroborative elucidation at the hands of careful clinical observation before it can command universal acceptance. Experiments upon animals will not suffice in this particular instance to decide the matter for the human family. Above all things it remains to be shown how and when, in the individual case, the dangerous microbes have effected their entrance into the system. Nor can we tell as yet why such an entrance takes place so easily in some cases, indeed occurs in a certain proportion of them with all the certainty of an inevitable doom. Again we are yet ignorant of the true reason why the same thing happens in other persons with tedious difficulty, and, as it were, only after the surmounting of formidable opposition on the part of a struggling constitution. And finally we have but very inadequate knowledge concerning the rationale of the well-attested fact that a large class of persons will refuse to contract phthisis at all, even under circumstances seemingly the most favorable for its acquisition.

These and other practical questions that suggest themselves in connection with phthisis, chronic pneumonia, and miliary tuberculosis, merit the earnest attention of the medical profession.

Drs. Biedert and Sigel have recently devoted much time to studies in this direction, and the results of a goodly series of careful clinical observations are published by them in the current number of *Virchow's Archiv*. The cases recently published by Dr. Kinnicutt and the writer (see THE MEDICAL RECORD, October 11 and 18, 1884) also show that the practitioner is liable at any time to be confronted with problems that may seem hopelessly puzzling, unless the new light of modern pathology can clear away the obscurity of some of their features.

Biedert and Sigel, in the article alluded to, directed their attention chiefly to the following points: In the first place they tried to determine the relation of the discovery in the sputum of tubercle-bacilli to the different clinical forms of consumption. Thus advanced phthisis and the incipient variety would presumably differ from each other, as well as from certain other pulmonary processes partaking of the nature of chronic inflammation. Then they wished to ascertain more definitely in what manner the appearance of increasing or decreasing proportions of bacilli, kept pace with the gross physical changes witnessed in their patients. And again they attempted to find out the precise conditions of the first appearance of bacilli in the sputum of persons already afflicted with pulmonary disease, and especially what effects were observable in such patients while living for long periods in the same rooms or wards with cases of pronounced phthisis.

It will not be possible here to follow the authors through the elaborate details of their painstaking investigations. They had an abundant clinical material that was put to the best possible use for deciding some of the problems and questions here barely indicated. The conclusions drawn from their observations may, however, profitably engage our attention. To begin with, they cannot regard the bacillus tuberculosis as distinguishable from all other bacteria by the mere peculiarity of its shape. They are not even quite certain that the color-test is sufficiently characteristic to invariably prevent all error. But, on the other hand, they fail to indicate any better method of differential recognition. In pronounced tubercular phthisis, Koch's bacilli are never found wanting from the sputum. Indeed, the presence of these microbes is the essential and vital point connected with that disease. Phthisis being by no means an affection that always starts at the apex of the lung, and being, moreover, a disease with at times misleading physical signs, the discovery of the specific micro-parasite is the one and only reliable and never-failing sign of its actual presence. Obviously the importance of this point, at least in a diagnostic point of view, can hardly be over-estimated. It amounts to the *de facto* existence of a symptom that is in the strictest sense pathognomonic. The discovery, in a given case, of the presence of tubercle bacilli would, then, according to these writers, have all the binding force of an irrefragable mathematical demonstration. And the diagnosis of tuberculosis would thus be capable of absolute scientific proof, possibly long before the grosser methods of physical examination could have revealed it.

But there occur, as we all know, obscure cases of insidious disease that are by many regarded as latent phthisis or possibly incipient consumption. The absence of bacilli in them would show that, as yet, tuberculosis is not present. Indeed, non-specific pulmonary infiltrations probably always precede the tubercular invasion. And there can be no doubt that such non-bacillary infiltrations may and commonly do accompany the specific lung lesions of true tuberculosis. The preponderance of one or the other of these distinct morbid processes may, perhaps, be gauged by comparing physical signs with the proportion of bacilli discoverable in the sputum.

In the course of the disease the non-specific lesion may assume the important rôle of acting as a barrier against the further encroachments of bacillary infiltration. On the other hand, it may happen that a comparatively harmless, because non-specific infiltration will furnish suitable soil for the growth and multiplication of the bacilli, and in that way exert a baneful influence on the health of the patient by its subsequent conversion into a specific infiltration.

The process which prepares the lung for the favorable reception of the bacilli is in itself a pathological one, being characterized by distinct cellular hyperplasia. It is noticeable that many of the new-formed cells have a spontaneous tendency toward degeneration. Nor can they long resist the virulent attacks of the micro-parasites. It would seem, however, that the latter are impotent to harm healthy cells. Indeed, they sooner or later perish in any conflict with normal tissue.

Biedert and Sigel further conclude from their observations that phthisis is not an infectious malady, and very certainly not a contagious one, in the usual sense. For consumption owes its origin not solely to the agency of an infectious virus upon a healthy organism. It distinctly needs preparatory changes, such as a vitiated constitution, lungs already damaged, or other predisposing elements, before a bacillary invasion can take hold and work further evil.

Even miliary tuberculosis has not been clinically shown to depend upon the introduction of large numbers of bacilli into previously healthy human lungs. Here, too, some morbid change must have been pre-wrought before the accidental inhalation of specific microbes can prove the starting-point of rapidly fatal disease.

If we accept as trustworthy the statements of these authors, it follows that the prophylaxis and rational treatment of phthisis are likely to remain in the near future, what they have been in the near past. That is to say, our attention must be directed chiefly toward constitutional improvement, with such hygienic and local measures as common-sense will dictate.

An anti-tubercular specific does not exist, and even should one be discovered it would be found impotent in those frequent cases where a vitiated constitution, an hereditary taint, lack of food, and unsanitary surroundings more than suffice to doom the poor human sufferer to an early grave. We may remember in this connection the words of Eisenmann: "Tubercles are but the tears of the poor shed within." It is not the wish of the writer to add to the length of this paper, which is based chiefly on the article of Biedert and Sigel, by an account of his own observations. The latter, although quite insignificant numerically, when compared with those of the authors mentioned, have nevertheless strengthened his belief in the substantial correctness of their views. Certainly there is a large field for further work here, a field rich in promise of practical results. It is to be hoped that the ground will not be allowed to lie fallow, and that our own country may contribute its contingent of faithful, tireless tillers in the twin cause of humanity and science.

The Kensington, 102 East Fifty-seventh Street,
December 13, 1884.

AN ANOMALY OF A VERTEBRA,

With a Suggestion Regarding the Causation of Certain Forms of Spinal Irritation.

By E. C. SPITZKA, M.D.,

Professor of Neuro-anatomy and Physiology in the New York Post-Graduate Medical School.

While examining some specimens in the anatomical collection of Professor William Darling, M.D., F.R.C.S., of this city, I was struck by a peculiarity of one of the vertebræ, which, without claiming a complete knowledge of the recorded anomalies, I believe has not been described. At all events, attention is not directed to it in any of the accessible handbooks.

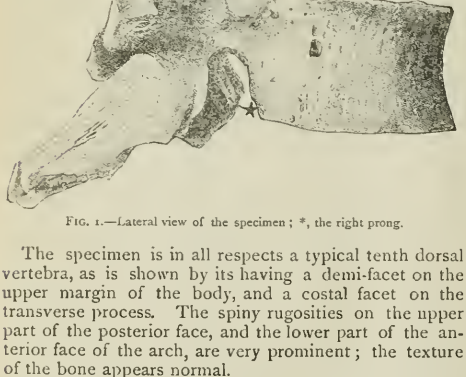

Fig. 1.—Lateral view of the specimen; *, the right prong.

The specimen is in all respects a typical tenth dorsal vertebra, as is shown by its having a demi-facet on the upper margin of the body, and a costal facet on the transverse process. The spiny rugosities on the upper part of the posterior face, and the lower part of the anterior face of the arch, are very prominent; the texture of the bone appears normal.

On the anterior face of the arch, immediately above the inferior articular processes, two powerful prongs of bone jut downward, as if—in the recent state, when the vertebræ were connected—to overlap the superior articular process of the next vertebra below. The disposition and dimensions of these prongs are so evident from the accompanying drawings, which are of the natural size, that I do not consider it necessary to tire the reader with a list of measurements.

Regarded laterally, it is clear that these processes must have encroached (particularly when the periosteal lining is considered to have been added) on the calibre of the intervertebral foramina (Fig. 1). Regarded from above, it is equally clear that they must have encroached on the spinal canal, whose contents here consist not alone of the cord and its membranes, but also of enormous descending nerve-trunks.

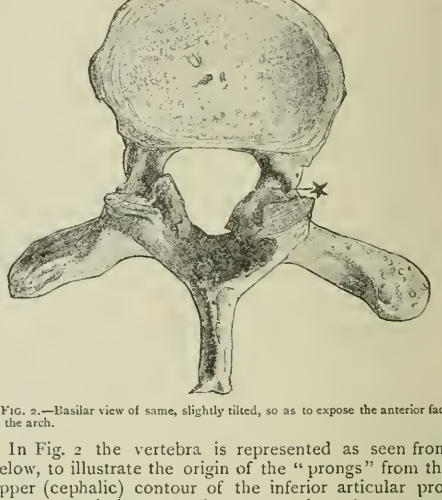

Fig. 2.—Basilar view of same, slightly tilted, so as to expose the anterior face of the arch.

In Fig. 2 the vertebra is represented as seen from below, to illustrate the origin of the "prongs" from the upper (cephalic) contour of the inferior articular processes. Their internal edge merges into the rugæ on the anterior face of the arch, of which they are probably hypertrophied continuations. The dorso-ventral face of the right prong turned toward the facet of the inferior articular process was rough, and showed an approach to the stalactite-like structure of the rugosities to which the vertebral ligaments are attached. This resemblance indicates to my mind the origin of these processes, namely, an ossification extending into the ligamentous structures, uniting the articular parts of the arches. That such a contrivance would render dislocation of the arches impossible is evident, and comparative anatomy furnishes more than one instance of a parallel proviso on the part of the vertebral fastenings.

The left upper articular process had an extension of bone glued to its anterior face, the separation was well indicated by the different character of the bone, and a deep ravine between them.

From the fact that the symptoms of spinal irritation are often localized around a single or one or two vertebræ, mechanical, thermal, or electrical applications to which often suffice to modify or provoke the numerous and variable subjective (and objective vaso-motor) symptoms of that disorder, it would seem plausible to connect this state with some irritating cause operating on the nerves at their exit, or the membranes of the cord and nerve-roots within the spinal canal. Injuries to the vertebral column, notably to the coccyx—as in three cases in my experience—are competent to provoke such symptoms, and it is not unlikely that such an hypertrophy of bone tissue as that described here may accompany or—developing spontaneously—cause this disorder. The

evil and apparently disproportionate effect of spiculæ pressing on the cranial dura, is an acknowledged dogma of neuropathology, and the analogy between that dogma and the explanation of spinal irritation here suggested is very great. In both cases the essential nervous tissues are not destructively involved, the primary tissue to suffer is the fibrous envelope. In both cases this fibrous envelope is supplied by nerves whose deep origin is in the contained neural viscus, and in both the functional effect is remote and usually manifests itself in the vaso-motor realm.

Six years ago I had referred to me, by Dr. H. Knapp, a school-teacher from the Carolinas, who suffered from aggravated spinal irritation. I became satisfied that a fracture or distortion of the upper part of the coccyx was the fundamental cause of her malady, and at my suggestion Dr. James L. Little removed the part below the point of union, which latter was at right angles. The patient returned to her home, and Dr. Knapp informed me that she was relieved of all her nervous symptoms. What is shown to be true of the coccyx in this case, where the *sublatâ causâ tollitur effectus* argument was so happily illustrated, is probably true of the more important parts of the vertebral column.

The condition of the vertebræ and their ligamentous structures has not been studied in connection with spinal irritation, and this very naturally, as such a study is difficult, involves much mutilation in a hurried autopsy, and autopsies in cases of spinal irritation are at best few. Nothing is known of the clinical history of the subject from whom this bone was derived, nor are other parts of its skeleton identifiable in the collection.

To Professor Darling my thanks are due for the loan of the specimen from which the accompanying drawings were made by the author.

Progress of Medical Science.

Tuberculosis of the Eye.—The *Revue Médicale*, October 18, 1884, gives the case of a child who, eight weeks after an injury to the eye, showed cheesy masses on the conjunctiva near the external canthus. On microscopical examination they were found to be tubercular infiltrations. The same journal also contains the following general remarks regarding ocular tuberculosis. The eye may be invaded by tubercle either primarily or secondarily. Every part of the organ where vascular tissue occurs may become the seat of tubercle. Thus it has been found in the iris, choroid, conjunctiva, and once or twice primary tubercle has been observed in the retina. The ciliary body may also be invaded by primary or secondary tubercle, the latter usually following a tubercular granuloma of the iris.

A French Treatment for Ulcer of the Leg.—Dr. Vidal recommends (*L'Union Médicale*, October 12, 1884) the following treatment, which he has found very efficacious, especially for indolent ulcers with pale base and ichorous secretion: First, wash the ulcer with an infusion of oak-leaves, then cover with a layer of subcarbonate of iron. A poultice of potato starch is then applied and retained by a roller bandage. Healing is complete in from ten to forty days. The subcarbonate of iron has an action upon the ulcer at the same time astringent and tonic. It gives new life and activity to the tissues. The galvanometer shows a considerable giving off of electricity, which explains, according to the author, the beneficial action of the iron.

Experimental Study of Chronic Alcoholism.—For the past three years Dujardin-Beaumetz and Andigé have been engaged in studying the effects of alcohol, chiefly upon pigs. The hog was chosen on account of the resemblance of the alimentary system with that of man, and for the further reason that the alcohol could be readily given. A variety of alcohols were experimented with, ranging from the high grade ethylic, at one hundred per cent., to the low grade beet-root, at thirty-four per cent. The daily dose was from one to two drachms to every ten pounds of live weight. This was given for thirty months, mixed with their daily food. In the intoxication produced, the stage of excitement was wanting, stupor being the first effect. The changes observed consisted in congestion and inflammation of the intestines, hyperæmia of the liver—not, however, going on to interstitial hepatitis—pulmonary congestion, and intramuscular hemorrhage. Hæmaturia and albuminuria were never present. The heart and kidneys were found fatty at times, but, as Cornil has previously shown, this is an almost constant condition in the pig. The lesions were much less marked in those experimented upon with the rectified and ethylic alcohols than in those given the poorer beet-root and potato alcohols.—*L'Union Médicale*, October 2, 1884.

The Dyspnœa of Bright's Disease.—A communication on the varieties of dyspnœa met with in Bright's disease, by Dr. Howard, of the McGill University (*Canada Medical and Surgical Journal*, November, 1884), illustrates the following points: 1. That marked dyspnœa may occur in Bright's disease not due to gross lesions in the lungs, pleura, or heart—such as inflammation or œdema of the lungs, hydrothorax, or pleurisy with effusion, endo- or peri-carditis, or valvular disease. 2. That it may be a continuous dyspnœa, or of paroxysmal character, resembling ordinary spasmodic asthma; and that these types may occur in the same case, although, in my experience, the continued variety is more frequent than the asthmatic. 3. That these forms of dyspnœa may occur as the prominent symptoms of renal disease, and their origin may escape recognition if the urine be not carefully examined, as well as the heart and pulse. 4. That Cheyne-Stokes respiration is often a symptom of Bright's disease, and that it obtains in both acute parenchymatous and in chronic interstitial nephritis. 5. That while usually an evidence that the fatal issue is near at hand, it may occur in a chronic form, and may occur for weeks, perhaps even for years. 6. That these several forms of dyspnœa just mentioned are very probably due to that defective renal elimination called uræmia. 7. That in the acute forms of Bright's disease, serious or fatal dyspnœa sometimes, but rarely, occurs in connection with effusion into the submucous membrane of the larynx (œdema glottidis).

Do Calcareous Concretions of the Lungs contain Bacilli?—The Paris correspondent of the *British Medical Journal* writes that M. Déjerine has made a series of researches to ascertain if the bacillus of tuberculosis is present in the calcareous concretions, surrounded by a zone of interstitial pneumonia, often observed at the apex of the lungs of old people. There are different varieties of these concretions; some are as hard as stone, others calcareous and cheesy, or as soft as pulp. In veritable cretaceous concretions, M. Déjerine only once ascertained the presence of two or three bacilli; these were used for inoculating rabbits, which, after seven months' interval, were entirely free from tuberculous lesion. In the calcareous cheesy masses the cretaceous concretion is always in the centre of the cheesy portion. M. Déjerine invariably detected bacilli in the non-calcareous part, and they contained more spores than the bacilli of a tuberculous lesion in the process of evolution. These remains of an arrested disease of parasitic origin are of special interest, as an examination may establish the distinction between the cheesy calcareous masses of tuberculosis, and similar degenerations found at the necropsies of syphilitic patients. M. Déjerine observes that the absence of bacilli does not necessarily prove that tuberculosis does not exist; he has been unable to detect the presence of a single bacillus, although the necropsy clearly demonstrated the presence of tuberculosis. M. Malassez says that the

spores of bacilli appear or disappear according to the coloring substance used. If fuchsine be used they assume the appearance of unbroken rods; if gentian violet, of spotted rods or a row of seeds. This difference of aspect may be interpreted in two different ways; it is possible that the substance which unites the seeds or spots can be colored by fuchsine and not by gentian it is also possible that the appearance is an optical effect due to the nature of the coloring substance.

Nephrectomy in Infants.—At a recent meeting of the London Clinical Society, Dr. Godlee reported a case of nephrectomy done in an infant. The child, a boy, aged one year and ten months, was admitted under his care at the Northeastern Hospital for Children in August, 1883. The tumor was first noticed in June, 1883, and was growing rapidly. It was on the right side, and measured four inches in the long diameter and about two in the short. It was freely movable, and manipulation caused no pain. There were no urinary symptoms at all. The kidney was removed by the lateral abdominal (Langenbuch's) incision, and was readily accomplished, as there were no adhesions to surrounding structures. The cæcum and the duodenum were the only pieces of bowel exposed. One large vein, which ran over the tumor, alone required ligature. There was no hemorrhage of consequence, and the whole operation was concluded in half an hour. The child had no symptoms of any kind after the operation. It ate and slept as well the next day as before, and the temperature only rose to 99° once, the day after the operation. It left the hospital, well, six days later. It continued well till February, 1884, when recurrence took place in the right iliac fossa and rapidly increased in size, passing down into the scrotum, and the child died soon after. Dr. Godlee mentioned eight other cases which have been recorded, showing that of them five had died of the immediate result of the operation, two had recovered well, but died afterward of a recurrence, and one was well when last heard of, but notwithstanding the unsatisfactory nature of the results he argued that, seeing how hopeless the condition is if left alone, we should endeavor to remove these tumors in a still earlier stage, at all events until it is proved that even this proceeding is invariably followed by a fatal result. He particularly, however, pleaded against attempting the removal of the very large growths which are not unfrequently met with, showing that they will almost certainly have involved surrounding structures, and that thus while no good can follow the operation an immediately fatal result is probable. The tumor weighed about one pound, and was in structure a mixed sarcoma, most of the cells being roundish or oval, but some spindle-shaped. This is probably the usual composition of these growths, but another class was mentioned in which striped muscular fibres occur. The latter are probably congenital, and often affect both kidneys, and are thus not favorable for surgical interference.

Blood-Poisoning Following Human Bites.—The Paris correspondent of the *London Lancet* reports two cases of this kind, which serve to illustrate the danger sometimes attending the infliction of human bites. A lad of eighteen, employed as a waiter at a public-house, was guilty of some misdemeanor, and while his employer was remonstrating with him, the lad, fearing a thrashing, took hold of the right hand of his master and bit him severely on the thumb. The publican dismissed the lad on the spot, had his thumb dressed, and thought no more about the matter. But about two months after the bite phlegmonous inflammation set in, and the patient was carried off in a few hours, death, according to the medical attendant, having been caused by blood-poisoning. In a recent quarrel between two newspaper editors in Paris, one bit the hand of the other, soon after which lymphangitis set in in the arm of the wounded patient, which was accompanied by symptoms of erysipelas, from which, however, he soon recovered.

Muscular Rupture simulating Abscess.—Dr. Phocas relates, in *La France Médicale*, September 25, 1884, a case of rupture of muscles in the lumbar region which simulated abscess and caused symptoms similar to those of lateral curvature of the spine. The patient, a young man, had first experienced pain in the left side. Three weeks later he began to walk with a limp and lean to the left side. He was, therefore, examined for lateral curvature. This was not found to exist, but a swelling to the left of the spinal column, painful on pressure and fluctuating in its central part, was made out. After repeated examinations it was regarded as an abscess and operated upon under chloroform. Careful dissection brought to light a rent in the lumbar aponeurosis, through which a hernia of the mass of sacro-lumbar muscles protruded. Underneath this hernia was a tumor covering the quadratus lumborum, and adherent to its outer border, as well as to the abdominal muscles and aponeurosis. The tumor measured about two inches in diameter, was of a yellowish color, of soft consistence, and fibrous aspect. Under the microscope it was found to be composed of altered muscular and fibrous tissue. The patient made a good recovery, and was soon able to leave the hospital, free from any signs of curvature, lameness, or deformity.

Sclerosis of the Coronary Arteries.—This condition has received more attention of late from both pathologists and clinicians, since the connection between pathological changes in the muscular tissue of the heart and diseases of its vessels has been better understood. Samuelson found that cutting off the circulation in the coronary arteries caused a notable diminution in the force of the cardiac contractions, and a corresponding lowering of the blood-pressure, while in some experiments by Cohnheim and Schulthess-Rechberg the heart continued to beat forcibly but somewhat irregularly and then suddenly stopped. The diseases of these vessels have been classified and described by Leyden upon the basis of an extensive clinical experience. Pathologically he distinguishes: 1. Sclerosis or ossification of the coronary arteries without any other cardiac lesion. The muscular wall is not diseased, and death occurs from some intercurrent affection. 2. Acute thrombotic softening or hemorrhagic infarction of the cardiac muscle following sclerotic thrombosis of the coronary arteries—*myomalacia cordis* of Ziegler. This leads eventually to fatty degeneration or softening of the region supplied by the occluded vessels, which is the most frequent cause of rupture of the heart. 3. The chronic form, fibrous degeneration of the muscular tissue—*myocarditis fibrosa*—arising from induration of the diseased vascular territory. At the apex aneurism of the heart frequently arises from this cause. 4. A combination of these several lesions. This is the most frequent condition.

Clinically these varieties occur in a more or less acute or chronic form. The author divides them into: 1. Cases running an acute course and ending in sudden death. Death occurs in syncope or after an attack of angina pectoris. The autopsy shows sometimes very marked, and sometimes very insignificant, anatomical changes in the heart-walls. These are rupture of the heart, sanguineous infiltration with effusion of blood into the pericardium, softening of the heart, or small patches of fatty degeneration in the muscular wall. To this form belong the cases described in the literature as embolism of the coronary arteries, a frequent symptom of which is a markedly slow pulse, or sudden paralysis of the heart may occur. 2. The subacute form, in which the course of the disease embraces a period of several weeks. The early symptoms are cough, shortness of breath, oppression, often attacks of angina pectoris, and sometimes dropsy. A slight improvement occurs, then the symptoms return with great severity and death ensues. After death we find myomalacia, sanguineous infiltration, fatty degeneration, and old fibrous bands. 3. The chronic cases usually described as chronic myocarditis, fibrous myocarditis, dilatation or aneurism of the heart. In per-

sons of advanced age cardiac symptoms appear gradually, having periods of abeyance. These symptoms are those of angina pectoris or cardiac asthma. The course is always progressive, and as the symptoms become more severe the patient presents a picture of severe heart disease. The asthma increases, dropsy occurs, and sometimes in delirium, sometimes suddenly, usually after suffering for several years, the patient succumbs.

Thus sclerosis of the coronary arteries presents itself as an acute or chronic disease, with more or less severe cardiac symptoms, occurring late in life, and independently of any valvular lesions. The heart symptoms are vital or physiological rather than physical. These are angina pectoris, asthma, cardiac weakness, syncope, and changes in the frequency and rhythm of the pulsations, the pulse being sometimes reduced to eight in the minute. The physical sign is that of dilatation of the left ventricle, with, usually, hypertrophy of the right. The signs on the part of the respiratory system are cough, dyspnœa, pulmonary engorgement, and occasionally also œdema of the lungs. The chief cause of the disease is heredity, although the abuse of alcoholic liquors and high living play a certain rôle in its production. Prolonged mental and physical exertion is also to be reckoned among the causes, and the author lends the weight of his authority to the popular belief of a "broken heart" from grief and anxiety.—*Centralblatt für Klinische Medicin*, No. 38, 1884.

The Etiology of Trichorrhexis Nodosa.—In opposition to the opinion of Eichhorst, who has recently written upon this condition, Dr. Wolffburg states that the sole cause of trichorrhexis nodosa is the improper care of the hair. He showed in his own person that it could be produced in the beard on one side by rubbing it energetically and frequently, the other side meanwhile being normal. The following are the grounds upon which the author bases his belief in the mechanical causation of trichorrhexis (*Centralblatt für Klinische Medicin*, No. 38, 1884): 1. The anatomical appearances—the hair, except for the nodules, is healthy. 2. The localization—the affection has hitherto been observed only in the larger hairs of the beard, and especially in those so situated as to be most exposed to mechanical injury when the face is rubbed, as in the beard covering the lower jaw. 3. The explanations hitherto offered are insufficient. 4. The supposed incurability of the affection is easily explained when one remembers that the treatment usually recommended (frictions with alcoholic preparations or irritating salves) only furnished new sources of irritation to the ill-treated beard.

The Prognosis of Spinal Curvatures.—The following are the principal conclusions of M. Pravaz in a recent article on the curability of deviations of the spinal column (*Centralblatt für Chirurgie*, No. 39, 1884): Of special importance in the prognosis of curvatures of the spine is the condition of the general health. The existence of any dyscrasia, especially of chlorosis, renders the prognosis less favorable. For in an individual suffering from mal-assimilation the skeleton is not sufficiently resisting to maintain the good results obtained by the use of apparatus; and sometimes in these cases there are such disorders of circulation as to interfere with the use of supports. In general, the younger the individual the more easily is the deformity overcome, yet it is the rule that the treatment must be longer continued in children than in adolescents, as it is less easy to adjust the apparatus for them, and the liability of relapses is greater. The author opposes forcibly the widespread error that curvatures of the spine will disappear as the child grows older. The curvatures following pleurisy are of unfavorable prognosis, as are also those produced by paresis of the spinal muscles. Of the deformities caused by disease of the osseous system those due to rachitis present the greatest difficulties in the way of treatment, for unless the deformity be overcome before the period of ebunration its correction becomes almost impossible. The prognosis of ordinary scoliosis depends greatly upon the amount of rotation present. When taken early in hand a curvature of even considerable extent may be overcome, as soon as the general health is improved. The prognosis of a dorsal curvature is more favorable than that of a lumbar deviation. Other things being equal, the curvatures with a long radius offer greater chances of cure than those with a short radius. This is because in the latter case the individual vertebræ are more wedge-shaped, and consequently are less likely to become restored to their normal dimensions.

The Antidote for Resorcin.—It having been remarked that in resorcin poisoning the arteries were nearly empty while the veins were engorged, Dr. Justus Andeer proposed the use of hot baths in order to deplete the venous system. He found, however, on experiment, that warm baths rather increased the severity of the symptoms caused by the resorcin poisoning. After casting about in several directions for an antidote, he finally discovered that the very best was good red wine—either Bordeaux or Burgundy. This acted equally well in slight and severe cases of poisoning from this substance. The author did not approve of the practice of giving an emetic, since by the time the dangerous symptoms had appeared the drug taken into the stomach had been entirely absorbed. If, however, there were any reason to suppose that such were not the case, the best emetic to employ was apomorphia given hypodermically. But red wine, he claims, is the true and certain antidote to resorcin.—*Wiener Medizinische Presse*, No. 38, 1884.

Minute Doses of Calomel in the Treatment of Pneumonia.—Dr. Droux de Chapois relates in the *Bulletin Général de Thérapeutique*, vol. cviii., No. 2, 1884, several cases of pneumonia in which resolution was delayed for a very long time, where an excellent result was obtained by fractional doses of calomel ($\frac{1}{15}$ grain) repeated every hour. He advises a recourse being had to this treatment whenever, despite the ordinary remedies, the symptoms grow worse instead of better, when the tongue becomes dry, and when the skin imparts a sensation of great heat and dryness to the finger. He mixes one grain of calomel with a teaspoonful of powdered sugar, and after it has been thoroughly stirred for some minutes divides it into twenty-five powders. Within twenty four, or at most forty-eight hours, he states, the skin becomes damp, the temperature falls, the tongue becomes moist, and the oppression diminishes. Sometimes a liquid stool occurs after fifteen or twenty doses have been taken; when this occurs the dose is reduced to $\frac{1}{60}$ grain every hour. Sometimes no stool occurs, but colicky pains are complained of. In this case it is not necessary to withhold the drug, but only to give a little magnesia with it.

The Chemical Poisons formed within the Intestinal Canal.—Dr. Netler concludes a long review on this subject as follows (*Archives Générales de Médecine*, October, 1884): The presence of inferior organisms produces, in the course of decomposition of nitrogenous matters, toxic substances of greater or less activity. These putrid poisons, or ptomaines, exist not only in putrefaction occurring without the body, but are present also normally in the digestive canal, and even in the blood. They play a very important part in pathology, and to them may be attributed: 1, poisoning by putrefactive matters, in which the poison, formed without the body, enters the organism by way of the intestinal canal or a wound; 2, putrid auto-intoxication, due to the action of ptomaines formed within the digestive tube; 3, the rôle of these ptomaines is very important, though at first sight less evident, in uræmia and acholia due to changes in the kidneys or liver. In these cases the alkaloids, not being excreted by the diseased organs, accumulate in the blood, and give rise to symptoms of poisoning.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 20, 1884.

THE NEW HEALTH BILL BEFORE CONGRESS.

IN a previous article we called the attention of the American Public Health Association, then about to assemble in St. Louis, to the importance of maturing measures thus early to be adopted and enforced in the event of an epidemic of cholera in this country. The questions which we raised were as to the best methods of securing concert of action of all State and municipal boards of health, and of bringing into active co-operation with these boards the General Government. The Association gave these subjects due consideration, and adopted a report embodying a scheme of prevention. In regard to cholera, the report advised the appointment and maintenance of medical officers of health at foreign ports, from which cholera may be brought, whose duty it shall be to inspect vessels bound to our ports, and give the requisite information, as to the existence or appearance of that disease, to the constituted authority in this country; a close alliance of our health authorities with those of the Dominion of Canada; the establishment and support of an inspection and quarantine service, like that inaugurated by the National Board of Health; aid of local boards by the General Government in the appropriation of necessary funds; the removal of local unsanitary conditions favorable to the development of cholera; isolation of first cases and destruction of infected materials; isolation of infected localities and towns, and intercourse with other towns under sanitary supervision.

Though the scheme embodies most of the precautions necessary to be taken to prevent a cholera epidemic, yet the plan lacks that continuity and coherence which a body embracing the foremost sanitary thinkers and workers of the United States ought to have formulated With the enemy three thousand miles away, and knowing precisely the route and the methods of its approach and invasion, a practical sanitarian ought to be able to state positively what steps must be taken to prevent, 1, the embarkation; 2, the transit; and, 3, the landing of this scourge on our shores. Evidently the first, and by far the most important duties in the scheme of prevention must be performed by the General Government, for it alone can regulate travel and traffic on the great ocean highways. The Association should not only have specifically stated what those duties are, but should have taken measures to ensure the necessary action of the Government. Cholera is not to be prevented by reports and proclamations, but by energetic work on the part of those who are appointed to protect the public health. To-day the obligation to prevent the introduction of cholera into this country rests solely with the National Government. No member of the Association doubts that, if the Government was thoroughly alive to its great responsibility and exercised its full power intelligently, it could prevent the importation of the germs of this or any other foreign pestilence. But will the Government act promptly, wisely, and effectively? That is the all-important question for the Association to determine, and if that body really intends to do more than put itself on record as proposing a few desultory and disconnected measures against the invasion of cholera, it has an immediate and pressing duty to perform. It should at once, through a competent committee, bring its intelligence and great influence to bear upon the Government, both in devising measures of prevention and aiding in their execution.

A step has been taken in the right direction by the State Boards of Health which, during the past week, held a Conference at Washington, reviewed the several questions involved in the scheme of prevention, and conferred with members of Congress and Government officials. This Conference did not, we believe, directly represent the Association, but stood alone as the representative of the State Boards of Health. The Association, therefore, has as yet taken no active steps to secure the adoption and enforcement of the measures of prevention which it recommended at St. Louis. Can it afford to remain idle during an epidemic of cholera with the mere statement of platitudes? We believe not. It has the necessary organization, through its executive and advisory committees, for immediate and aggressive work, and it will sadly come short of its duty and its high prerogatives if it does not become a potent factor in organizing and sustaining measures of defence. In this preliminary movement of the State Boards of Health, in holding a conference at Washington, the Association should have been represented, in order to aid in maturing those plans which it should co-operate in carrying into effect.

The Conference of State Boards found an anomalous condition of affairs at Washington, and sought to remedy it by preparing a bill to be submitted to Congress. This bill provides for the organization of a National Board of Health, to be composed of one representative from each existing State Board of Health. The remaining provisions of the bill are designed to render the board the efficient agent of the Government in the prevention of epidemics. The purposes of the Conference are good and commendable, though perhaps the objects sought might have been obtained more directly and immediately. Certainly we need—nay, must have—a National Board of Health competent to employ wisely and efficiently the powers of the General Government in the protection of the public health. But those who seek such legislation as the Conference contemplates should be well advised of the obstacles in their way, and the nature of the opposition which they will meet. There is already a National Board of Health, fully organized and equipped to perform all the functions which this bill imposes upon a new board. Let the Con-

ference inquire into the history of the defeat of this board and it will discover an agent in the Treasury Department hostile to all further health legislation, unless such legislation places under his control the public funds appropriated for sanitary purposes. We refer to the chief medical officer of the Marine Hospital Service. To this source must be referred whatever miscarriage there has been of proper support of the existing board by Congress, and it is from this source will come the secret influences which will tend powerfully to defeat all proper health legislation during the present session. In undertaking, therefore, to secure the favorable action of Congress on its bill the Conference must be prepared to encounter and overcome the opposition which a bureau, already in possession by artful intrigues of the funds and the power belonging to the existing board, can wield through the Treasury Department.

MORPHINISM DETECTED THROUGH THE EXAMINATION OF THE URINE.

MORPHIOMANIA has been growing so rapidly and withal so quietly in our country that its present proportions are hardly realized, even by the profession. It is not alone to the specialist, nor to the physician who has a home and a method for the cure of the opium-habit that the subject is of interest, the general practitioner may at any moment meet with cases of a more or less pronounced character.

The ruses resorted to by many patients to obtain their favorite drug, and the great facilities they have of secret indulgence, tend at times to mislead and render treatment unsatisfactory.

Again, in the therapy of ordinary diseases in morphine takers, our remedies may be counteracted or their effects modified to an extent incompatible with recovery. It may become important for us to discover, therefore, if the drug is being taken surreptitiously.

It has been claimed by many that morphia becomes so changed in the system that no traces of the alkaloid, as such, are to be found in the tissues or excretions. On the other hand, several observers hold an opposite view. On account of the diversity of opinion in competent observers and the practical significance of the entire subject, Dr. Notta has made some careful investigations, touching the elimination of morphia by the kidneys. He has published the results of his research in *L'Union Médicale*. At first he used Mayer's test, by the double iodide of potassium and mercury, then that of Bouchardat. Both of these proved unsatisfactory, giving positive results only where the daily quantity of urine was small.

Thus, Mayer's test gave a characteristic precipitate only when each quart of urine contained at least three grains of the alkaloid. Bouchardat's test gave reliable results when as little as one to two grains were present.

The author's own method, which he recommends as simple, exact, and rapid, is as follows:

Treat a quart of the suspected urine with subacetate of lead (1 to 10). The precipitate is a combination of the lead with the uric, phosphoric, and other acids existing in the urine and the coloring matters and the extractives.

The decolorized urine then contains the morphine combined with acetic acid, the substances not precipitable by the sub-acetate of lead, and the excess of the lead. Now filter and get rid of the lead by adding sulphuric acid (1 to 10), drop by drop until there is no further precipitate. Filter again, add an excess of ammonia and warm amylic alcohol and shake. The mixture soon becomes clear and holds in solution all the morphine previously in the urine. After this it is only necessary to shake this solution with water acidulated with sulphuric acid in order to obtain the morphia as a sulphate. This is decomposed with ammonia water and taken up again with amylic alcohol, and after evaporation we have the morphine, which can be tested with the usual tests.

The conclusions which Notta draws from his investigations are: that morphine is eliminated, in great part at least, by the kidneys, provided they are not diseased; that Mayer's or Bouchardat's tests can be employed after eliminating sugar and albumen, but that when these tests fail, the one here given, or some equally reliable one must be employed. That it is always possible to find the drug in the urine of an habitual morphine taker provided as much as $1\frac{2}{3}$ grain is taken per day.

Further experiments must be made to decide whether this test discovers morphine in such cases as acute poisoning, or if it is only reliable in such cases as were here tested, where the drug had been taken for a long time in large quantities.

THE COLLECTIVE INVESTIGATION RECORD OF THE BRITISH MEDICAL ASSOCIATION.

THE *Bristol Medico-chirurgical Journal* is not satisfied with the labors so far published by the British Collective Investigation Committee, and takes the promoters of the scheme severely to task. It makes some remarks, which strike us as being decidedly forcible, even if not altogether merited.

Referring to the second volume of this committee, which deals principally with pneumonia, and which has been previously noticed in our columns, it says:

"Probably no scheme for the advancement of medical science was ever started under more favorable auspices than this collective investigation one of the British Medical Association. Prominent leaders in the profession praised and promoted it on platform, paper, and committee in the metropolis; and emissaries of accredited talent and eloquence were sent into the provinces to preach to us this new gospel of scientific research. Everywhere their doctrines have been received with a chorus of assent. Questions in scientific medicine were to be answered by the overwhelming mass, and not by the unsupported individual; the untrustworthiness of individual labors in the closet was to be replaced by the generalized experiences of the practitioner in public; and the groping investigations of the medical theorist were to be supplemented, or rather replaced, by the accurate records of the practical worker, as figures, facts, and statistics. *Parturiunt montes, nascetur*—let us see what."

The *Journal* then shows that from the sum expended by the Association they had a right to expect some noteworthy contribution to medical knowledge. It then continues as follows:

"We have systematized for us, under various headings,

the reports of 1,065 cases. The first thing one naturally turns to is the trustworthiness of the reporters. The men who are most likely to give us satisfactory answers to the queries propounded are the various teachers in our medical schools, the physicians to our hospitals, the men whom, in consultation or general practice, we know to have most experience of the complaint and most knowledge of it. We have gone carefully over the names of those who have made the returns, and we have discovered among them scarcely one which, either from general reputation in these islands or from local reputation in our own district, deserves to be heard as of any authority. That our hospital and consulting physicians practically ignore these inquisitive cards there can be no doubt. The fact is patent to any one who looks. These are the men who see most of the disease, and know most of the subject, and who are most competent to give returns. Why do they ignore the queries? Do they distrust the process? We fear there is no other explanation possible. To begin with, therefore, it submits that those most competent to answer refuse to do so, and the trustworthiness of the report is thus, in the first place, weakened."

The practical outcome of the replies of all these practitioners, in the writer's own words, is this: "It is manifest that the lines of treatment are so various as not to permit of any value being attached to a comparison of mortality. Surely this is the classical mouse of the mountains in travail at last!"

In conclusion, the *Journal* thinks that polling impressions of its practitioners is not the way to promote science. "The variables and contingencies are so numerous and so important that they cannot, as in this instance, be ignored. To ignore these is to nullify the whole work. And even if the results of this questioning were to be quite trustworthy, drawn up, criticised, and tabulated by skilled observers, we fail to see what new truth this galloping over the surface of disease can bring forth. We have been galloping over disease for centuries, and the outcomes are abundant enough in myriads of works in a score of languages. We want nowadays to attack disease from the bottom. The work must be one of concentrated labor by the most penetrating intellects, with every opportunity to study disease at the bedside and in the laboratory, and not of vague recollections jotted down in the midst of other pursuits by the rank and file, and huddled into columns by committees. No doubt the Collective Investigation Committee will soon come to a natural and timely end; in the meantime we would express our regret that so much money of the British Medical Association, which might go to its excellent benevolent fund, should be expended on an undertaking so palpably useless as this one."

PRECOCIOUS CANCER OF THE STOMACH.

The difficulties that at times surround the diagnosis of cancer of the stomach are well known. When the symptoms are indistinct and the physical exploration unsatisfactory, cancer is sometimes excluded on account of the youth of the individual. For by common consent carcinoma of the stomach is regarded as of rare occurrence before the age of forty. Yet we are often enough surprised to find at an autopsy a gastric cancer, where no suspicion of the disease existed during the lifetime of the patient.

Dr. Mathieu, of Lyon, has recently made a special study of carcinoma of the stomach, as it occurs early in life.

From the literature of the subject he has collected twenty-seven cases, most of which were observed before the age of thirty. The author separates them into three groups.

The first comprises those cases in which a diagnosis was made of some entirely different disease. This happened nine times. The diagnosis of cirrhosis being made five times, cancer of the liver, aneurism of the aorta, tumor of the spleen, and pleurisy, each once.

The second group contains eight cases. Here the difficulty was located in the digestive tract, its cancerous nature, however, not being recognized. Pregnancy existed in four of the patients belonging to this group, and the persistent vomiting was regarded as that common to their condition. Only one patient had hæmatemesis, which came on shortly before death. The disease was put down as dyspepsia in one case, and in another as ulcer of the stomach.

The third group finally includes those cases in which a correct diagnosis was reached, the tumor being made out in every instance. It would appear, therefore, that two-thirds of these cases passed unrecognized, and were mistaken for diseases that had no connection with the digestive tract. The course of gastric cancer of early life is, according to Mathieu, rapidly fatal, characteristic cachexia is commonly absent, and hæmatemesis quite rare. It seems, therefore, that the disease does not fully conform to the usual type of cancer, as ordinarily seen later in life.

THE CLINICAL FORMS OF HEPATIC COLIC.

Among the painful affections of the abdominal viscera few are more distressing, and oftentimes difficult to relieve, than the various forms of hepatic colic.

Dr. Olive, of Paris, has recently made a study of hepatic colic, from a purely clinical standpoint, a review of which is published in the *Journal de Médecine*, October 18, 1884. Among the principal causes of hepatic colic he finds arthritism, with its various manifestations, such as obesity, diabetes, and calculus; forced repose, sadness, sedentary occupations, abuse of alcohol, a diet too exclusively animal or fatty, and different chronic affections of the liver also invite colic.

The immediate determining causes are those which produce violent jars to the abdominal organs, such as horseback riding, the jolting of vehicles, and the like.

The author describes a form of colic which he terms pseudo-gastralgic-hepatic colic, which he differentiates from gastralgia by the following characteristics:

The patient suffering from gastralgia has more frequent pains, and would not go for three or four months without suffering, as the pseudo-gastralgic patient often does. Gastralgia causes distress when the stomach is empty, and at or just after a meal. The time for pseudo-gastralgia to appear is usually about two hours after eating.

The pains come on suddenly in hepatic colic, less so in gastralgia. They radiate toward the shoulder in hepatic colic, but not in gastralgia.

Still there may be a reflex intercostal neuralgia accompanying the latter affection. After hepatic colic, even without icterus, the urine is commonly red, and contains biliary pigment. This is never the case in gastralgia pure and simple.

FURTHER PATHOLOGICAL AND THERAPEUTICAL CONTRIBUTIONS TO CHOLERA.

The number of contributions to the subject of cholera is increasing rather faster than they can be recorded. Professor B. Grassi, in the *Gazz. degli Ospitali*, states that he has found the comma-bacilli in the stools of persons suffering from choleraic diarrhœa, or cholerine. The patient whose dejecta was examined was a soldier in a regiment of which some members had been attacked with cholera. Professor Grassi, together with Drs. Vivanti and Berretta, added to the number of bacilli repasts by swallowing dried cholera-bacilli. They experienced no ill effects. Professor Grassi believes that flies are active and important agents in spreading cholera. Professor Cantani, in the same journal, reports the results of some of his examinations of the blood in cholera patients. He finds that with the progress of the disease the blood lessens in alkalinity and finally at death is actually acid. He infers from this fact (which was known before) that if venous injections be made in treating the disease the liquid used ought to be more alkaline than that hitherto employed.

Dr. Manfredi has studied the action of tannic acid upon cholera-bacilli and finds that even in small amounts it kills them. He therefore recommends the rectal injection of solutions of this drug. Cantani recommends the same method and gives the following formula :

℞. Aq. catid.....	2000	grammes.
Acid. tannic	5-6-10	"
Gum arab.....	50	"
Tr. opii.....	30-50	gtt.

M.

Professor Alberta Riva, as the result of experiments upon animals, thinks that saline injections made into the pleural cavity, or preferably into the peritoneal cavity, may be beneficial in cholera.

Dr. Panier, in *El Siglo Medico*, recommends the heroic use of strychnine throughout the whole course of cholera. He gives hourly about gr. $\frac{1}{60}$ of sulphate of strychnia. MM. Huchard and Dujardin-Beaumetz recommend the hypodermic injection of caffeine dissolved in a solution of benzoate of soda. The dose given is about gr. jss.

Le Progrès Médicale quotes the results of the treatment of cholera with injections of chloral hydrate by Dr. Reddié, of Partabgark, India. He employed injections of small doses of chloral hydrate. Thirty-five per cent. of his cases died, while under other treatment the mortality was sixty-four per cent.

The Last New Antipyretic is thallin, and it has been introduced by Dr. V. Jaksch, of Vienna. It is one of the chinolin compounds, and is a powerful antifermentative. Jaksch has used it in eighty-six cases, and found that, although a powerful antipyretic, it is by no means a specific.

News of the Week.

The Biological Department of the University of Pennsylvania was formally opened on the 4th instant by Provost William Pepper. Addresses were made by Drs. Harrison Allen and Joseph Leidy.

The State Board of Lunacy of Pennsylvania have been diligently investigating the condition of the State Asylums since August last. As a result, says the *Medical Times*, they have been able to report to the State Board eighteen cases of alleged improper treatment which they had investigated, in some of which gross neglect and wanton cruelty had been practised. Several of these have been already removed to State hospitals, and new cases are constantly coming to light.

Death of Dr. Henry Gibbons.—We regret to announce the death of Dr. Henry Gibbons, of San Francisco, Cal., in the seventy-sixth year of his age. Dr. Gibbons was born in Wilmington, Del. He graduated in medicine from the University of Pennsylvania, in 1829. In 1850 he moved to San Francisco. He established and successfully conducted the *Pacific Medical and Surgical Journal*. He was also one of the founders of and teachers in the Medical College of the Pacific. He was a member of the Society of Friends.

The Bacillus of Syphilis.—Dr. Sigmund Lustgarten, describes a "specific bacillus of syphilis" (*Wiener Medicin. Wochen.*, No. 47, 1884) which he has discovered in the initial lesions and in gummata of syphilis. It is of about the same size and appearance as the tubercle bacillus and lies in small groups enclosed in the somewhat swollen lymphoid cells. The organism is distinguished from other bacilli by its staining and peculiar grouping. The investigations of previous discoverers of syphilis-germs are characterized as being "tinctured with grave errors."

The Death of Dr. James G. Thomas, of Savannah, Ga., recently occurred under unusually painful circumstances. Dr. Thomas was a member of the Executive Committee of the Ninth International Congress. He took a deep interest in the success of the Congress, and, at a considerable sacrifice, came to Washington, November 29th, to attend the meeting for organization. While on the way he was seized with a violent chill, and on his arrival at once took to his bed, from which he never again arose, the disease proving to be acute lobar pneumonia. He may be said to have lost his life in the service of the Congress, and it is an irreparable loss to the Executive Committee, as well as to his bereaved family and his fellow-citizens of Savannah and of Georgia.

Importation of Rags.—The Treasury Department has decided that no old rags shall be landed in the United States except upon disinfection by one of the following processes : 1. Boiling in water for two hours under a pressure of fifty pounds per square inch. 2. Boiling in water for four hours without pressure. 3. Subjection to the action of confined sulphurous-acid gas for six hours, burning one and a half or two pounds roll brimstone in each 1,000 cubic feet of space, with the rags well scattered upon racks. 4. Disinfection in the bale by means

of perforated screws or tubes through which sulphur dioxide, or superheated steam at a temperature of not less than 350 degrees, shall be forced under a pressure of four atmospheres for a period sufficient to insure thorough disinfection.

The Presbyterian Hospital.—A lady has promised to give $50,000 to the Presbyterian Hospital for the purpose of erecting a new wing, provided an equal sum is raised by other parties.

Trained Nurses for the Insane.—A special committee of the State Charities Aid Association has prepared a report upon the training of nurses for the insane. The committee has secured the co-operation of the Bellevue Training School, and is now occupied in maturing a plan by which a certain number of women trained there as nurses for the sick may secure in one of our lunatic asylums a special training in the care of the insane.

Deaths of Foreign Medical Men.—The past few weeks has witnessed the death of a number of prominent European medical men. In France we have chronicled the death of M. Fauvel, the distinguished Vice-president of the Académie de Médecine. We learn that Professor Fonssagrives, of the Montpellier Faculty of Medicine has recently died of cholera. In Germany, the deaths are announced of Professor v. Wittich, of Königsberg, and Professor K. v. Vierordt, of Tübingen. Professor Kolbe, of Leipzig, and Professor Chvostek, of Vienna, also recently died.

Medical Diplomas in Australia.—A physician of Pictou, N. S. W., has been refused a license to practise because, although he had a degree of M.D., granted by the University *of Philadelphia*, yet it only certified to his studying for three years. The authorities as well as the medical journals make the mistake of thinking that the degree and the University are all right.

Gift to a German Hospital.—The German Hospital of Philadelphia has recently been enlarged and greatly improved. The sum of $600,000, which covers the expense of the changes, was given to the hospital by Mr. John D. Lakenau, President of the Board of Trustees.

Hayem's Formula for Intra-Venous Injection in Cholera :

Aquæ distillat.....	1 litre.
Sodii chlorid. pur.....	5 grammes.
Sodii sulphat. pur.....	10 grammes.

M. Filter and give two to two and a half litres at a temperature of 38° C. The time occupied in giving is twelve to fifteen minutes.

Dr. Louis H. Steiner has just been elected librarian of the new Pratt Free Library in Baltimore, which has been completed at a cost of $1,000,000.

Death During a Foot-ball Match.—Another death is recorded as occurring at a foot-ball match between students of St. Thomas' Hospital, London. The victim was a young man, aged twenty-three, who, while in the midst of the game, suddenly staggered and fell down dead.

The Rabbeth Memorial.—A thousand dollars have already been collected for this purpose.

Dr. Jay Owens retires from the editorship of the *Northwestern Lancet*. He is succeeded by Dr. C. B. Witherle.

The Loneliest Doctor in the World is the ophthalmologist who hasn't written an article on cocaine.

The Use of Iodide of Potassium in Large Doses.—Dr. W. C. Dabney, of Charlottesville, Va., calls our attention to a clinical lecture by Charcot, published in *Le Progrès Médical* for January 13, 1877, and showing that Charcot had used potassium iodide in doses of six to ten grammes daily since 1874.

Ovariotomy in Rome.—Dr. J. H. Thompson, of Rome, Italy, sends us the records of a case of ovariotomy performed by himself recently, and regarding which there were several points of more than ordinary interest. He writes: "Ovariotomy in Rome has generally been unsuccessful, I think owing to the fact that it has mostly been performed in hospitals which were built in the fifteenth century (persons who had the ability to pay for home attention generally preferring to go to London). These old buildings cannot be made aseptic." This case was operated upon in a specially provided apartment. It was complicated with pregnancy. We regret that the report is too long for publication by us.

THE TEXT OF THE NEW HEALTH BILL.

The following is the text of the new Health Bill, prepared by the National Conference of State Boards of Health, now before Congress :

To amend an Act entitled "An Act to prevent the introduction of contagious and infectious diseases into the United States and to establish a National Board of Health."

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That an Act entitled, "An Act to prevent the introduction of contagious and infectious diseases into the United States and to establish a National Board of Health," approved March 3, 1879, be so amended as to provide that there shall be established a National Board of Health, to consist of one member from each State Board of Health now established, or which may be hereafter established in the United States, to be appointed by the President and confirmed by the Senate, whose compensation, when actually engaged in the performance of duty under this act, shall be ten dollars per diem each, and reasonable expenses. This board shall meet in Washington within ninety days after the passage of this Act, and shall meet in Washington annually, and in case of emergency upon the call of its chairman and secretary, or upon the extraordinary call of the President of the United States, as hereinafter provided.

The officers of this board shall be a chairman and secretary. The secretary shall be the executive officer of and ex-officio a member of the board, and shall devote his entire time to the duties of the office, and may be removed for cause, at any regular meeting of the board, two-thirds of the full board voting therefor, and shall receive such salary as may be determined by the board. The chairman with six other members, representing the various geographical divisions of the country, shall constitute the executive committee of the board, to be elected at the first meeting of the board, and at each annual meeting thereafter, and said committee shall, and is hereby authorized to exercise such powers as may from time to time be conferred upon it by the board.

Section 2. The duties of this board shall be, and it is

hereby authorized and given power to make or cause to be made, such investigations at any place within the United States, or at any foreign port or place, and to collect information upon all matters relating to the public health, and to frame such rules and regulations as may be necessary for the government of the quarantine service of the United States; and all the power and authority now provided by law, or which may be provided by law, for the control and protection of the public health of the United States, shall be and are hereby vested in said board, except as to the special authority vested in the President of the United States under the provisions of this act. The rules and regulations of this board shall severally be executed, under the direction of this board, through such Departments of the Government, or other officers, as the law may prescribe or the President may designate.

This board shall co-operate with, and so far as it lawfully may, shall aid State and local boards of health in the enforcement of the rules and regulations of such boards, to prevent the entroduction of contagious and infectious diseases from foreign countries into the United States, and into one State from another.

SECTION 3. It shall be the duty of this board to make such rules and regulations as are necessary to be observed by vessels at ports of departure, where such vessels sail from any foreign port or place to any port or place in the United States, to secure the best sanitary condition of such vessel, her cargo, passengers, and crew, and to prepare from time to time for the consular officers of the United States, and for the medical officers serving under this act at any foreign port, and otherwise make publicly known such rules and regulations, which, when approved by the President and issued by the Department of State, and posted in the office of the consul or other representatives of the United States at such foreign ports for at least ten days, shall be enforced by the consular officers and agents of the United States.

SECTION 4. It shall be unlawful for any vessel from any foreign port or place to enter any port in the United States, except in accordance with the rules and regulations made in pursuance of this act, and of the rules and regulations made under State or municipal authority, and any such vessel which shall attempt to enter any port of the United States in violation thereof, shall be liable to process in the proper district court of the United States, and upon conviction, shall forfeit to the United States a sum to be awarded in the discretion of the court, not exceeding $1,000, which shall be a lien upon such vessel, to be recovered upon proceeding in the proper district court of the United States, in accordance with the rules and laws governing cases of seizure of vessels for violation of the revenue laws, and in all such cases the United States Attorney for such district shall appear on behalf of the United States; and all such vessels shall obtain from the consular or authorized medical officer at the port of departure a certificate in duplicate, setting forth the sanitary history of said vessel, and that it has in all respects complied with the rules and regulations of this board, made in pursuance of this act for the government of such vessels, and before granting such certificate such consular or medical officer is required to be satisfied that the statements therein made are true; and upon the request of this board, the President of the United States is hereby authorized to appoint proper medical officers, to serve in the offices of the consuls at any such foreign ports, to make the inspections and give the certificates herein required.

SECTION 5. Such vessels shall observe all rules and regulations made by this board in pursuance of this act, in regard to the inspection, disinfection, and isolation of the same, upon its arrival at any port in the United States, and for the treatment of persons and cargo on board, so as to prevent the introduction of contagious diseases into the United States, and it shall be unlawful for any vessel to enter such port, to land its passengers or discharge its cargo, except upon a certificate from the health officer of such port, that such rules and regulations have in all respects been complied with.

SECTION 6. In the event of any sudden emergency, threatening the importation of contagious or infectious disease into the United States from any foreign country, the President of the United States is hereby authorized and required, in his discretion, to adopt and make known forthwith by public proclamation, such measures as may meet the emergency, either by suspending the introduction into the United States by land or sea, of any specific merchandise calculated to be a vehicle for the communication of contagion, or by prohibiting the entry into the ports of the United States of vessels coming from infected countries or having contagious or infectious disease on board. And in case the President shall at any time exercise the authority hereby conferred upon him, he shall, at or before the time of issuing such proclamation as aforesaid, convene the National Board of Health, to meet at Washington in special session within ten days from the date of such notice of convention, and the said board shall thereupon advise such measures as it may deem sufficient to meet the emergency; and upon the taking effect of such measures, with the approval of the President of the United States as herein provided, the President's proclamation aforesaid shall cease to have effect. It shall be the duty of this Board at all times to give prompt attention to any question in sanitary science which may be submitted to it by the President.

SECTION 7. It shall be the duty of the Department of State to obtain from the consular officers at foreign ports or places all available information in regard to the sanitary condition of such ports and places, and to transmit the same to this board; and it shall be the duty of this board to obtain from the State and municipal health authorities throughout the United States, and from all other available sources, weekly reports of the sanitary condition of ports and places within the United States, and reports and other matters relating to climatic and other conditions affecting the public health, and it shall prepare, publish, and transmit to State and other authorities, and other proper persons, weekly abstracts of such reports, consular reports, and other useful information relating to the public health; and it shall make to the President, for transmission to Congress, an annual report of its transactions, with such recommendations as it may deem important to the public health; and the necessary printing of the board shall be done at the Government Printing Office, upon the requisition of the secretary of such board, in the same manner and subject to the same provisions as other public printing for the several Departments of the Government.

SECTION 8. The President of the United States is authorized, when requested by this board, and when the same can be done without prejudice to the public service, to detail officers from the several Departments of the Government, for temporary duty, to act under the direction of this board in carrying out the provisions of this act, and such officers shall receive no additional compensation, except for actual and necessary expenses incurred in the performance of such duties.

SECTION 9. To meet the expenses incurred in carrying out the provisions of this act, the sum of $500,000, or so much thereof as may be necessary, is hereby appropriated, to be disbursed under the direction of the board; and the board shall have authority to appoint such disbursing agents as it deems necessary, who shall give bond, as in other cases, for the faithful performance of their duties.

SECTION 10. All acts and parts of acts in conflict with any of the provisions of this act shall be and are hereby repealed.

EXONERATED.—We are pleased to state that the physicians who were censured by the Coroner in the Jaeger case have been fully exonerated. Thus ends what might have proved to have been a professional scandal.]

Reviews and Notices.

THE PRINCIPLES AND PRACTICE OF GYNECOLOGY. By THOMAS ADDIS EMMET, M.D., LL.D., etc. Third edition, thoroughly revised. With 150 illustrations. Philadelphia: Henry C. Lea's Sons & Co. 1884.

THE originality and amplitude of resource which characterize the operative procedures of the author are faithfully mirrored in the goodly volume before us.

The first and second editions of this book are so well known to the profession that it would be an act of supererogation to enter into a discussion of the merits of the third edition, were the latter merely a reprint of the former. We have essentially an almost new work before us.

Honesty of purpose, truthfulness of clinical description, love of his art, tempered by judicious fairness—these qualities speak in every chapter of the book. It is seldom that the personal character of an author is so correctly reflected as we find it in Dr. Emmet's writings. To read his description of cases and commentaries is almost equivalent to seeing, hearing, and knowing him. Those who enjoy the latter privilege are satisfied that the teachings of our author are based upon sincere conviction, deduced from an ample clinical material. If some of these teachings are at variance with the accepted views of the majority of gynecologists, it behooves the latter to bear in mind the character of the author as a man and physician, and to study with more than usual care the new doctrines and operative measures which he propounds with all the earnestness of his nature. Dr. Emmet simplifies the treatment of diseases of women materially in that he not only asserts "that pelvic cellulitis is by far the most important disease with which woman is afflicted," but that he refuses to recognize the distinctions usually made by authors between the various inflammatory conditions in the vicinity of the uterus. "The terms perimetritis and parametritis are not applicable, as they express a theoretical distinction only, and the difference cannot be recognized clinically." These dicta mark a decided departure from established doctrine and raise Dr. Emmet to the dignity of founding a new school in gynecology. Without entering into the argument, chiefly clinical, by means of which he seeks to establish these radical views, it may be granted that, if the generalization of utero-pelvic inflammation does not accrue to the detriment of patients suffering from these diseases, we cannot demur with justice. A fine analytical diagnosis is "a thing of beauty," but it is not "a joy forever" if it conduce not to the recovery of the patient. In this respect the aim of science is fulfilled by Dr. Emmet's classification. The management of these cases is greatly simplified, and its success is vouched for by the logic of facts. The clinical history of cellulitis, its etiology and treatment, are drawn with a master pen; but nowhere in this volume does the author's cautious attention to minute details, which is the key to his success, appear more pronounced than in the enunciation of the lines of treatment. Prolonged hot water injections in the early stage, and less abundant injections continued in the later stages, are the chief reliance.

The question arises: Will Dr. Emmet's radical views on cellulitis as a fundamental agency in uterine troubles be accepted by the profession? Our answer is, that these views have already received practical indorsement, and are thus daily accepted by every gynecologist, when he prescribes hot-water injections. That the latter is the most universal remedy in uterine disease, is a well-recognized fact. Its recommendation by Dr. Emmet rapidly introduced it; its success, as a chief or auxiliary measure, has maintained its position. It is Dr. Emmet's chief remedy in all shades of cellulitis, and he has thus ingeniously, perhaps unintentionally, brought the profession to a recognition of the correctness of his views in the most practical manner.

One of the distinguishing features of the present edition of the work, is the fact that several new operations are described, one of which, at least, is destined to win for itself a lasting place among restorative procedures in plastic gynecology. This is, we believe, true of Dr. Emmet's new operation for restoration of the posterior wall of the vagina in the "so-called rupture of the perineum." The author claims that it is "exceedingly doubtful if the perineum can be lacerated without the tear extending through the sphincter ani." He recognizes the latter alone as a true rupture of the perineum, for which the well-known operation, described in former editions, is still recommended. The larger number of "perineal lacerations," however, are "due to overstretching of the pelvic fascia, or to laceration at some point of fascia and muscle." To remedy the damage inflicted by this complication of labor, Dr. Emmet gives the profession a new operation which appears to be perfect in its immediate result, viz., the restoration of the normal configuration and dimensions of the vagina. Upon this point we speak from actual observation. We find the new operation not difficult of execution, and the claim that it contributes to the diminution of pain in the period of healing, seems to be substantiated. It is to be regretted, however, that it will be difficult to comprehend the steps of this operative procedure from the illustrations in the book. Two additional diagrams, viz., one representing the process of denudation in its proper line, and another showing by dotted lines wherein the new operation differs from and is superior to the old operation, would materially facilitate its comprehension. It is to be hoped that in the next edition, if not in a separate paper, Dr. Emmet will favor the profession with a drawing which will be as superior to Fig. 67, in the delineation of the new operation for restoration of the posterior vaginal wall, as is Fig. 89 of the last edition superior to Fig. 83 of the first, in the illustration of the operation for lacerated cervix.

The new operation, when finished, leaves the vagina in an almost virginal state, with the fourchette sloping inward, while the old operation builds a dam in front of the vagina, which sooner or later yields in many cases. If space permitted, we would be glad to enter into a more detailed discussion and description of this operation, as we have seen it under the hands of its skilful designer.

Another decided advance brought prominently forward in Dr. Emmet's last edition, but foreshadowed in the second, is the "button-hole operation" for the relief of those distressing urethral and bladder troubles which are the bane of many a woman's life, and the despair of many a doctor. The illustration of this operation is simply perfect, as is also the description of the steps of, and the indications for, its performance. The author claims more for it than we would at the present time be willing to admit. But there is no doubt that the great benefits which this ingenious procedure opens out in hitherto incurable cases, will very soon be appreciated. The beautiful imitation of the ordinary button-hole, which prevents irritation of the wound edges, together with the fact that incontinence of urine does not result from the mutilation of the urethra, mark this procedure as one of the most brilliant achievements of surgery.

The recognition of cellulitis as a dominant element in gynecic troubles; the introduction of hot-water douches for their treatment; the operation for lacerated cervix; the button-hole operation in urethra and bladder; the ingenious and effective operation for repair of injuries in the posterior vaginal wall—these original and practical contributions form a pedestal upon which Dr. Emmet's fame must securely rest. If his fertile brain and skilful hand furnish naught else to the profession but these, he may be content in the knowledge that he has created an era in practical gynecology to whose opening future generations of physicians will ever turn with reverence and gratitude.

We have dwelt briefly upon the chief distinguishing characteristics of this third edition of Dr. Emmet's work, and we have, therefore, been forced to omit mention of many valuable features. Altogether, the work before us is an inexhaustible fountain of clinical information, which no practitioner who has the interest of his clientèle at heart can afford to miss from his library. Its practical teachings render it indispensable to the general practitioner, while its novel views and operations commend it to the progressive gynecologist. It is almost a new book, for, as the author tells us, "The chapters on The Relation of Education and Social Condition to Development; those on Pelvic Cellulitis; on the Diseases of the Ovary; on Ovariotomy, and on Stone in the Bladder, have been nearly rewritten. The chapters on Prolapse of the Vaginal Walls; on Laceration of the Vaginal Outlet and through the Sphincter and Perineum; on the Methods of Partial and Complete Removal of the Uterus for Malignant Disease; on the Surgical Treatment of Fibrous Tumors; on Diseases of the Fallopian Tubes; and on Diseases of the Urethra, are essentially new, containing the views and experience of the author in a form which has not been presented to the profession before."

The type is clear, although somewhat condensed to make room for additional matter; the illustrations in the main are good.

The Formation of Poisons by Micro-organisms. By G. V. Black, M.D., D.D.S. 8vo, pp. 178. Philadelphia: P. Blakiston, Son & Co. 1884.

The author of this little work possesses in an unusual degree the faculty of seizing the main points of an argument and presenting them clearly and forcibly. He lays no claim to originality in his facts, and if he has made any investigations of his own on the subject, he does not obtrude them in his book, but gives the history and present standing of the subject in a concise and yet comprehensive manner, such as no other work with which we are acquainted furnishes. That part of the treatise in which he endeavors to explain the *modus operandi* of the bacteria and their congeners by the poisonous effects of their waste products is a truly delightful piece of logical reasoning, and will do much to enable the reader to obtain an understanding of the deadly work of the micro-organisms. The author argues *à priori* by analogy, and having, by a general consideration of the laws of digestion and assimilation, made out a probability for his theory, he proceeds to substantiate it by the facts as far as known. We have no hesitation in pronouncing it the best book for students, physicians, and scientists, who desire to have in a clear and condensed form a knowledge and understanding of the germ theory of disease.

A Pharmacopœia for the Treatment of Diseases of the Larynx, Pharynx, and Nasal Passages. By G. M. Lefferts, A.M., M.D. Second Edition, Revised and Enlarged. New York and London: G. P. Putnam's Sons. 1884.

Dr. Lefferts' little volume forms a convenient collection of the commoner formulæ requisite for treating the diseases of the upper air-passages. It is a work that the general practitioner will at times consult with profit to himself and his patients.

The Ear: Its Anatomy, Physiology, and Diseases. A Practical Treatise for the Use of Medical Students and Practitioners. By Charles H. Burnett, A.M., M.D. With One Hundred and Seven Illustrations. Second Edition, Revised and Rewritten. Pp. 585. Philadelphia: Henry C. Lea's Son & Co. 1884.

Seven years have elapsed since the publication of the first edition of this work; in this time the advances in the science of otology have been rapid and of an eminently practical character, so that in the work of revision for this second edition of the treatise the author found many alterations necessary; portions of the book had to be entirely rewritten, whilst much material found to be obsolete was omitted.

Dr. Burnett seems to have entered on the laborious task of giving the profession a complete treatise on the ear at a most auspicious moment, since he brings to the work a ripe experience both as practitioner and writer; and by acknowledging his indebtedness to both the valuable contributions of his American *confrères*, and of the accumulated knowledge of German, English, French, and other laborers in the field of otology the conceit of writing a book merely from the narrow standpoint of individual experience is notably absent.

The author informs us in the preface that special attention has been given in the present edition to the following subjects, namely: the abnormalities of the auricle, otomycosis, the treatment of aural polypi, and the diagnosis, etiology, and treatment of aural vertigo. The work is divided into sections as follows:

Part I.—Anatomy and physiology of the external ear, comprising the auricle, the external auditory canal, and the membrana tympani. The middle ear: The tympanic cavity, the Eustachian tube, and mastoid portion. The internal ear: The labyrinth and auditory nerve, and scheme of relationship between the middle and internal ear.

Part II.—The examination of patients, the necessary instruments and their employment, the consideration of sound, hearing, and tests of the latter, organic defects of the auricle, and its cutaneous affections, including morbid growths and injuries, diseases of the external auditory canal, foreign bodies in the external ear, and the results of inflammation and injury, affections of the membrana tympani, including acute and chronic inflammation, injuries and morbid growths.

Under the section devoted to the middle ear are considered acute and chronic catarrhal inflammation of the middle ear and their treatment, functional disturbances, noises in the head, etc., and organic disturbances. Chapters are assigned to acute and purulent inflammation of the middle ear, their course and consequences.

Section VI. is devoted to diseases of the internal ear, and Section VII. to deaf-mutes, and partially deaf children, the methods of their relief and education.

While the otologist might differ from the author in many minor points of theory and practice, the student and practitioner will find this work fully up to the present time in all of the subjects of which it treats, and a safe guide to follow in practice. The various topics pertaining to otology have been handled with unwearied zeal and patience; indeed the literature of the subject has been so exhaustively brought forth that the reviewer is at a loss to know just where to take up the thread of the text for practical criticism. Perhaps it might be said the author has introduced some instruments for the examination of the ear which cannot be practically adopted by the specialist even; but, after all, this has a certain interest as showing what efforts have been made to increase our means of finding out more about the diseases of the ear. The author adheres to the employment of the hard-rubber nose-piece in inflation of the tympanum by means of the air-bag; this appliance has long fallen into disuse in New York, where a glass bulb is used to close up the meatus of one nostril, a method less disagreeable to the patient and more cleanly than the insertion of a long slender tube into the nose. The above are trivial matters, after all, and one would scarcely be warranted in taking up further space in an analytical examination of all the points of interest, since the work is likely soon to be in the hands of every one interested in the subject.

Otologists must thank Dr. Burnett for taking a step in advance in the matter of aural nomenclature, and, although there is yet some room left for improvement in this respect, he has left a better state of things than previously existed. The book is well made up, and the illustrations are good in the main; the economy of the publishers, however, in producing inferior pictures o,

the human face, as shown in the explanatory cuts, cannot be commended.

On the whole this treatise will be an invaluable acquisition to the library of the American practitioner; the subjects are conveniently arranged for reference, and the index will be found unusually complete.

THE PHYSICIAN'S VISITING LIST FOR 1885. Philadelphia: P. Blakiston, Son & Co.

THIS popular visiting list appears in its thirty-fourth year. There are no changes in the plan of its arrangement.

MICRO-ORGANISMS AND DISEASE. By E. KLEIN, M.D., F.R.S. London: Macmillan & Co. 1884.

THIS little volume is a reprint of a series of articles that were published in the *London Practitioner*. It is by no means a complete treatise, but may serve as a convenient introduction to the study of microbes in their relation to disease.

A TEXT-BOOK OF PATHOLOGICAL ANATOMY AND PATHOGENESIS. By ERNEST ZIEGLER. Translated and Edited for English Students by DONALD MACALISTER, M.A., M.B. Part II. Special Pathological Anatomy, Sections 1–8. Pp. 365. New York: William Wood & Co. 1884. Wood's Library of Standard Medical Authors.

THE editor and translator of this work, Dr. MacAlister, states that he had expected to make the present volume the concluding one. Owing to the great demand for the first sections, however, Professor Ziegler was unable to complete his work as early as expected. The present volume does not, therefore, finish the work. It takes up the various branches of special pathology, beginning with blood and lymph and ending with the alimentary tract and the liver and pancreas. The kidneys, lungs, and nervous system remain yet to be treated of.

We can hardly praise too highly this volume. It treats every branch of the subject with a most satisfactory completeness, yet it is not prolix, nor does it deal in hypotheses or superfluous discussion. Numerous bibliographical references are given. The illustrations are excellent and vastly superior to what we are accustomed to find in this series. The work when completed will take its place as the best pathological text-book in the English language.

THE ELEMENTS OF PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY: A Handbook for Medical Students and Practitioners, containing a general account of Nutrition, Foods, and Digestion, and the Chemistry of the Tissues, Organs, Secretions, and Excretions of the Body in Health and Disease, together with Methods of Preparing or Separating their Chief Constituents, as also for their Examination in Detail, and an Outline Syllabus of a Practical Course of Instruction for Students. By T. CRANSTOUN CHARLES, M.D. Illustrated with 38 engravings on wood and a chromo-lithograph. 8vo, pp. 463. Philadelphia: Henry C. Lea's Son & Co. 1884.

THE very ample title-page which is given above gives so full an idea of the scope of the author's work that an analytical review is hardly necessary. Dr. Charles, as his title-page would almost indicate, is fully impressed with the importance and practical reach of his book. A perusal of its contents, or rather of selected portions thereof, shows that the author's confidence in himself is not misplaced, and that he has not only got hold of an important branch of medical science, but has treated it in a competent and instructive manner. The physician, however, must be impressed, in reading this as well as many other of the works that are pouring so rapidly from the medical press, that his work of acquiring knowledge is never done, and that the fields in which he can and perhaps ought to acquire technical skill are rapidly multiplying. If he chooses to take up physiological and pathological chemistry we cannot recommend a better work than the present. In fact it fills a gap in medical text-books, and that is a thing which can be rarely said nowadays.

Physiological chemistry generally means in practice urinary analysis. In accordance with this fact, Dr. Charles has devoted much space to the elucidation of urinary mysteries. He does this with much detail, and yet in a practical and intelligible manner. In fact, the author has filled his book with many practical hints, as well as with recondite formulæ and complicated reactions. It is needless to say that the volume is published in the best style.

ON SCLEROSIS OF THE SPINAL CORD: Including Locomotor Ataxia, Spastic Spinal Paralysis, and other System Diseases of the Spinal Cord, their Pathology, Symptoms, Diagnosis, and Treatment. By JULIUS ALTHAUS, M.D., M.R.C.P. With nine engravings, pp. 394. New York: G. P. Putnam's Sons. 1885.

THE physician in general practice is doubtless sometimes a little puzzled at the extradorinary amount of attention bestowed upon locomotor ataxia by neurologists. It is a rare disease. Among a million of people only two or three die from it annually, and the country practitioner sees only two or three cases in as many decades. But tabes dorsalis is, scientifically, a most interesting affair, and, practically, when it does occur it means years of distress and agony to the patient. No one will find fault, therefore, at the attempts to secure more knowledge of its nature and more skill in its treatment. Dr. Althaus' book is really a treatise on locomotor ataxia, with a few chapters on the other scleroses added for completeness. It embodies some of the articles that have already appeared in English medical journals. Taken altogether, it is a most interesting and practical contribution to the subject. The author is of the opinion that a great deal can be done for tabes if taken early, and he is especially earnest in urging that the general practitioner be made familiar with the premonitory symptoms of the disease.

Dr. Althaus believes thoroughly in the great importance which syphilis plays in the etiology of the disease. For this reason he makes iodide of potassium a prominent drug in his armamentarium. He commends ergot and electricity highly. Nitrate of silver is spoken of with more caution.

The book is written in a plain and non-technical style, and will be found attractive and instructive by all classes of medical men.

HENKE'S ATLAS OF SURGICAL ANATOMY. Translated and Edited by W. A. ROTHACKER, M.D., Pathologist to the Cincinnati Hospital and Lecturer on Pathological Anatomy in Miami Medical College. 4to, with 81 plates and 123 figures. Cincinnati: A. E. Wilde & Co. 1884.

THE well-known German Atlas of Henke, on regional and surgical anatomy, has now for the first time been reproduced in this country. It comes to us in a form worthy of the original, the acknowledged excellence of which has rendered changes and additions unnecessary. As the American editor implies in his preface, it is essentially a working Atlas, and will be found valuable by the busy practitioner, as a convenient book of anatomical and surgical reference.

TREATMENT OF DISEASES OF WOMEN, PUERPERAL AND NON-PUERPERAL. By CHARLES H. GOODWIN, M.D. Second Edition. New York: C. H. Goodwin. 1884.

A SECOND edition of Dr. Goodwin's Treatment of Diseases of Women has just appeared. The work, it is stated, has been revised, but differs in no material respect from its first issue. It is a compilation of the late views of many of New York's most eminent obstetricians and gynecologists, and as such commends itself to those who have either not the time to read these various writers *in extenso* or to whom their original contributions are inaccessible. We cannot commend it too highly.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS.

Stated Meeting, November 28th, 1884.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

ANTEFLEXION OF THE UTERUS AND ITS ASSOCIATED PATHOLOGICAL CONDITIONS—THEIR PREVENTION AND TREATMENT.

DR. W. GILL WYLIE read a paper on the above subject, which was the continuation of a paper previously published in the *American Journal of Obstetries*. The present paper referred especially to the prevention and treatment of anteflexion.

Prevention.—The true etiology of the disease indicates the steps to be taken to prevent it. As long as delicate children are born and are able to reach maturity, women will suffer with small, imperfectly formed and degenerated genital organs. We might expect to find anteflexed uteri among these children, although born of healthy parents. To prevent anteflexion or imperfect development and degeneration of the generative organs children with good constitutions should be kept in good health until fully matured, and delicate and stunted children should be so treated as to increase their physical strength and have a surplus force for the development of the organs of generation.

Local treatment, if given at all, should aim at stimulating healthy development.

Treatment.—These cases usually seek medical advice on account of dysmenorrhœa or irregular menstruation. Yet not unfrequently a woman will bear with the pain for years, and finally consult a physician for sterility.

Dr. Wylie rarely makes a local examination in unmarried women for either dysmenorrhœa or amenorrhœa without first trying the effect of general treatment. By far the most common type among the well-to-do classes is that where imperfect development is plainly indicated. In Sims' position, with his speculum in place, a properly curved sound can be readily passed to the os internum; at this point there may be some resistance, and as the instrument passes the patient usually complains of sharp pain. The fundus may be found sensitive to the touch of the sound, and not unfrequently its withdrawal is followed by blood, although it may have been passed with the greatest care. He usually begins the local treatment of such a case by inserting a small piece of borated cotton, saturated with pure glycerine, against the anterior lip of the cervix, crowding it somewhat back into the vagina. The cotton rolls into a ball which tends to displace the cervix backward and lift the fundus. A string is attached to the cotton, by means of which the patient can remove it, which she is instructed to do in twenty-four hours. The pledgets are put in two or three times a week until the patient bears the vaginal examination without pain. The patient is also instructed to use hot-water-vaginal douches during the intervening days. If the case is complicated by peri-uterine congestion or subacute inflammation, the simple glycerine pledgets are replaced by similar pledgets saturated with a mixture of alum, one part to pure glycerine fifteen parts, and sufficient carbolic acid to act as a disinfectant, usually one drachm to the pint. The size of the pledgets is gradually increased. As a rule an ordinary case will change much in two or three weeks by this preparatory treatment. Occasionally six or eight weeks of such treatment will be required before the next step can be safely undertaken.

Dilatation.—The patient being in Sims' position, the vagina is sponged out with a solution of 1 to 3,000 of bichloride, or 1 to 20 of carbolic acid. All instruments are kept in a solution of carbolic acid. Then the Sims' uterine dilator is inserted into the uterine canal. The dilator when properly curved can be passed almost as easily as the sound. The blades should be forced apart about two lines. The amount of force required for this amount of dilatation will vary very greatly, but usually in old cases it is considerable, especially those of an imperfectly developed type. This procedure causes more or less, and in some cases, intense pain. The dilator is withdrawn and the cervical director introduced to the os internum. The applicator, previously wrapped with cotton, is dipped into pure carbolic acid, the free acid having been rubbed off, and is passed through the tube of the director directly to the os internum, and thoroughly applied by turning it about and slightly withdrawing the tube and applicator. About twenty grains of iodoform are blown against the cervix as the speculum is withdrawn. In some cases the pain is immediately relieved. Rarely, the patient complains of pain for several hours. When properly performed, as directed above, and if antiseptic precautions were used, he had never seen any harm from this treatment. The first dilatation can be made at the patient's home, and she is kept in bed for the rest of the day, or until all disturbance has ceased. As a rule, it is best to allow at least a week to pass before the dilatation is repeated. The glycerine pledgets can be inserted as usual in the meantime. Sometimes he repeats the dilatation three times between the menses, but usually twice is sufficient, and if the dilatation can be carried to a point where the blades are four lines apart at the os externum, the dysmenorrhœa is relieved in the majority of cases where there is no active endocarditis, or endo-cervicitis, and in the majority of cases it is the beginning of a permanent cure.

In married women, if nothing is done to prevent impregnation, sterility will often be cured by this simple treatment, but in certain cases the method causes only temporary relief, and it becomes necessary to resort to Sims' operation, which is division or divulsion and incision, with the use of a glass-plug or some pessary, or, what he liked better, a hard rubber drainage-tube containing deep grooves.

Dr. Wylie performs Sims' operation with some modification. He divides the posterior wall of the cervix in the median line for half an inch or more, according to the length of the infra-vaginal part. The lining membrane is divided the full length of the cervix, and the muscular walls are also divided for some distance under the external mucous membrane covering the infra-vaginal cervix. He regarded it as a mistake to divide all the muscles, and especially the vaginal mucous membrane of the cervix as far as to the vaginal junction. After this incision the dilator is introduced and the os internum freely divulsed. Dr. Sims always divided the anterior wall at the os internum, but Dr. Wylie had lately trusted to the dilators to overcome all of the constriction at this point, for he had never seen a full-sized plug introduced after incision as far as the os internum without the free use of the dilator. The dilatation should be done slowly so as to give time for the tissues to stretch and not to tear.

Dr. Wylie had never believed in the necessity of the bilateral operation. In those cases where Dr. Sims recommended it he would dilate or divulse and keep open with a drainage-tube. If the dilatation is imperfectly done the relief is only temporary, but when thoroughly done and repeated, say twice in two or three months, it will often effect a permanent cure in cases of even ten years' standing. Child-bearing is the best means of complete development and making a permanent cure in such cases.

Sponge-tents.—For more than ten years he had not used tents in these cases.

Dilatation by sound.—The uterus is too movable and elastic to permit of the use of sounds to the best advantage, and many cases have been sounded up to the os in-

ternum and not beyond. Still he had to confess that we could more easily dispense with the uterotome than with uterine dilators, but dilators could do serious harm when dilatation was carried too far, and if one use a screw to force open the dilators the risk was greater than when he used his hand or hands to regulate the amount of dilatation.

If the use of *pessaries* in anteflexion had never been taught, much harm would have been averted, and more progress made in the right direction. As to the use of stem-pessaries for straightening the canal they may do good by stimulating development, but many of them are dangerous instruments. In some cases he used a drainage-tube of hard rubber with one or more deep grooves in it, the object being to keep up perfect drainage, but not with the idea of using a splint on the fractured or bent uterus.

Dr. Wylie then spoke of the complications, and gave the following conclusions to which he had arrived:

First.—There is undoubtedly a certain number of cases in which a marked degree of anterior curvature gives no painful symptoms.

Second.—Anterior displacements are the result rather than the cause of pathological changes in the uterus. They may add to, and sometimes intensify, disease, but are rarely, if ever, the primary cause.

Third.—Dysmenorrhœa with anteflexion is rarely, if ever, chiefly and directly due to the flexion, but the latter in some cases may aggravate the pathological conditions which are the real cause of the pain.

Fourth.—The attempt to correct anterior displacements by the use of pessaries is rarely, if ever, sufficient to effect a cure unless the cervix is dilated at the same time, or other pathological conditions are treated. The use of mechanical supports may give some relief, but they are often merely palliative, and, as used by many, they frequently do harm.

Fifth.—The true morbid condition of the uterus in most cases of anteflexion is one of imperfect development, while the uterine canal is more or less stenosed by the degeneration and contraction of the uterine tissues, and the mucous lining is degenerated and atrophied, often hyperæsthetic, especially in that part of the organ where the circular fibres are most powerful and contracted, namely, at the os internum.

Sixth.—If the above is true, the treatment obviously would be to stimulate development by improving the general health and by the local use of electricity, to relieve the stenosis by dilatation, or division and divulsion, to effect drainage, and to bring about a healthy condition of the mucous lining.

Dr. H. T. Hanks said he was certainly very thankful to Dr. Wylie for his excellent paper upon this subject, especially because it was a subject worthy of consideration by gynecologists. He had been very much interested in the statement made by Professor Thomas in his address before the New York State Medical Association, namely, that there was such a thing as curing anteflexion and dysmenorrhœa by rapid and forcible divulsion, and he thought many of us had yet to learn that this procedure could be resorted to with almost uniform benefit. Dr. Hanks believed that four-fifths of all cases of anteflexion which needed treatment could be cured by rapid and forcible dilatation. The results of treatment in his cases had been the same as Dr. Wylie had reported; that is, he had effected cure in thirty-three or four out of thirty-five cases. He had found the hard-rubber dilators to which his name had been attached as serviceable, in the majority of cases, as any instrument which could be employed. He had used the instruments recommended by Dr. Ball, Dr. Sims, Dr. Goodell, Dr. Ellinger, and others, and they were excellent instruments.

One reason for resorting to this method of treatment was the fact that there was no deformity after rapid and forcible divulsion, and there was no doubt that a new condition of the tissues was established as a result of the thickening which took place after the operation, and which in some cases requires some little time to remove. If the canal is dilated to fifteen or eighteen, American scale, it will not contract, as some had supposed.

With reference to after-treatment, he always kept his patients in bed for six or eight days, and more or less under the influence of opium. It might not be necessary but he had always done it, and had not had pelvic peritonitis develop until his patients had gotten up and been about the house, and it was evident that the pelvic inflammation was due to some indiscretion.

With reference to instruments he thought that Dr. Ball's, if it could be bent, would be better than any which had been devised.

There was one peculiarity which he wished to mention, and it was that dilatation was apparently done by pressing the hands together, but it would be noticed that the points of the instrument within the internal os did not always dilate so much as was supposed.

He did not claim so much for the hard-rubber dilators as formerly, but he always knew when one passed through the internal os, and the operator always knew just how much the internal os was dilated. He thought that this was one of the advantages which the hard-rubber dilator had over the Sims or the Peaslee sound.

Another advantage which the hard-rubber instrument gave was that it could be turned over and retroflexion of the uterus produced. In this manner the anterior wall of the cervix was stretched somewhat, which he had thought was of some advantage. However, either instrument could do the work well in the hands of skilled operators.

The Chairman had been especially pleased to hear Dr. Wylie direct attention in his paper to the necessity of having the patient in a good general condition before resorting to any operation. Some years ago he performed rapid dilatation in many cases, and produced pelvic cellulitis in many instances, and in some pelvic peritonitis, and while Dr. Hanks had expressed the urgent desire that the teaching of the treatment by rapid dilatation should be repeated frequently, the Chairman hoped that with each instruction there would be given the caution that the pelvic organs should be in as healthy a condition as possible under the circumstances, before resorting to any operative procedure, as he had become abundantly satisfied that the ill results which followed in his cases were due to the lack of this preparatory treatment.

With reference to instruments, he thought a good deal depended upon the dexterity of the operator. A man was very poorly qualified to dilate the cervix if he was unable to say whether or not the instrument had entered the os internum.

Some years ago he devised an instrument for dilating the os internum, and thought that it, more than any other instrument, was capable of entering that portion of the canal with the greatest ease, and it had the capacity of dilating the internal os to any extent desired.

Notwithstanding, he thought he had gained a great deal in the way of the dilator, it seemed to him that the best dilator was the circular wedge, especially for the uterine canal.

With reference to the point made by Dr. Hanks concerning the capacity of the instrument to retroflex the uterus, it was a question whether that manipulation would be allowable in very many cases, because the violence done in the dilatation of the os internum was about as much as could safely be endured at one sitting, particularly if the patient was not under an anæsthetic.

Dr. Hanks thought no judicious surgeon would attempt to dilate the uterine canal without thoroughly anæsthetizing his patient. With regard to sounds, no one should attempt to use an instrument larger than a small Simpson sound, if he wished to dilate without an anæsthetic.

The Chairman directed attention to two other points

which Dr. Wylie had mentioned. First, Dr. Wylie seldom makes an incision in the anterior wall of the cervix, and in that he departs from the method employed by Dr. Sims and does so without giving his reasons. It would seem that if the incision was necessary at all it would be necessary at that point.

The Chairman also suggested whether it would not be well to introduce a smaller pessary with an olive bulb to prevent union after the incision had been made.

The author of the paper also made reference to the rubber stem pessary with a groove in its side. The chairman supposed the preference for the hard rubber was the fact that the groove could not be made in glass. Other things being equal, he should prefer glass. The chairman then exhibited several glass tubes which he had used, having a hole through the centre, and they had been made so strong that it was impossible to break them with the fingers.

Dr. Sell said that if there was any comparison to be made between divulsion in the cervix uteri and the same procedure in the urethra of the male, he would say that the plan advocated by Dr. Wylie was very much the best.

He could not exactly say that we had reached the time when dilators, such as Peaslee's, should be altogether thrown aside. He had used them when divulsion was not in vogue, and had succeeded in curing his patients.

He had been pleased to hear that the best method of treatment was pregnancy, and he had succeeded in many cases with the introduction of Peaslee's sound; sometimes he used a tent, occasionally slightly nicking the cervix just sufficiently to admit the probe, in establishing a condition which permitted pregnancy and cure of the patient. He was especially pleased with the remarks made by Dr. Wylie concerning the preparatory treatment, but did not hear anything especial with reference to medical treatment, as such, in these cases. Dr. Sell then spoke of the beneficial effects produced by the internal administration of certain remedies, such as helonias, caulophyllum, cimicifuga, nux vomica, etc. With reference to the use of pessaries, he thought that they could be used, not to abuse the patient and set up inflammation, but as tampons are used with reference to special conditions. He believed in preparatory treatment, and, when the patient had reached a certain point, a pessary could be used with advantage, and then by the internal administration of remedies the dysmenorrhœa could be overcome, the leucorrhœa relieved, and a cure would follow in very many cases.

Dr. A. M. Jacobus had seen Dr. Wylie operate upon a large number of cases with and without anæsthetics, and had seen most excellent results follow. It might be better to resort to an anæsthetic, but there were very many cases in which divulsion could be practised safely without an anæsthetic. He had not seen a patient die after divulsion, and he had seen a fatal result follow very slight dilatation and with a steel sound. He thought that after the patient had passed two or three years of menstrual life without being relieved, local treatment should be begun to develop the uterus, and that the patient in consequence would be less likely to require future treatment for the dysmenorrhœa and sterility.

He did not believe that there was a single antiflexion pessary which could be used with safety. Of all the instruments which he had employed, or seen used, he preferred that used by Dr. Wylie to any other.

With regard to preparatory treatment, it was exceedingly important, as had already been mentioned by Dr. Wylie. He thought that the uterus could be straightened up considerably by means of the tampon, so much so that the divulsor could be used later without special difficulty.

Dr. Wylie, in closing the discussion, said that he had not had a single case of cellulitis occur as a result of operative procedure in private practice. Further, that he had no special faith in the efficacy of remedies, any more than that they might improve the general condition, and in that way help a weak organ. He thought probably that electricity would do more good than any special remedies which might be administered internally. His faith in treating symptoms had not been very great. As to the use of pessaries, he was satisfied that practically they were of but little value, although he was aware that some of our very best men employed them a great deal. The great trouble was that when a gynecologist was thoroughly interested in a pessary he was very apt to make the patient fit the pessary instead of the pessary fitting the patient. He also thought that glass was preferable to hard rubber for the plugs as a general rule, but it being so much more difficult to obtain he had substituted the hard rubber.

The reason why he had not performed Dr. Sims' operation was because he had found that by slightly dilating the canal, merely enough to give free drainage, the circulation of the mucous membrane had been improved, and then by the application of remedies the development and improvement of its general condition had been so great that it had been unnecessary to resort to further procedure. He had not found it necessary to give an anæsthetic unless the tissue of the cervix was very hard.

Dr. Wylie's reasons for not cutting the os internum was because he looked upon it very much as a sphincter, and if he wished to remove its spasmodic action he did not cut it, but dilated it a little, and then tore the tissues beneath the mucous membrane. Besides, he had seen Dr. Sims cut and then fail to introduce the glass plug. Again, when he found that he could accomplish with the divulsor what Dr. Sims had endeavored to do with the knife first and then using the divulsor, he had ceased to use the knife. The ease with which the cervix elongates had caused him to use the divulsor, holding the cervix firmly with the tenaculum.

When he dilates, as he called it, he did it only after he became perfectly familiar with the case, had given it preparatory treatment, and had learned the complications. If it was a case which did not need divulsion then he dilated. He resorted to divulsion or the use of the knife in not more than one in six, perhaps ten, cases where ten years ago he would have resorted to these measures, simply because he had found that dilatation would accomplish all that was desired. When he divulsed it was in cases in which he had resorted first to preparatory treatment and then to dilatation, and finally adopted divulsion because dilatation did not effect a cure. When he divulses he generally does it with the patient under the influence of ether, and he would put them to bed and keep them there, not for three or four days, but for two weeks. He never allows them to rise from the bed with the stem pessary or drainage-tube in position, unless it is absolutely necessary. He prefers, as a rule, to have the patient wear the tube after one menstruation; that is, remove it during menstruation and wear it afterward.

Dr. Sell said he had used electricity, and had found it an excellent method of treatment. He would further remark that dispensary treatment was somewhat different from that which could be adopted in private practice, and thought it well to have medicinal means to resort to independent of operative procedure.

The Chairman referred to one point which he had noticed in seeing Dr. Wylie operate, namely, that the pressure made upon the handles of the divulsor was intermittent, and that the instrument was turned slightly at short intervals, so that the intra-uterine pressure was brought to bear upon all parts of the circumference of the cervical canal.

The Swallowing of a Shawl-pin.—Dr. F. W. Smith, of Syracuse, N. Y., writes that he was called to see a woman who had accidentally swallowed a shawl-pin four and a half inches long. She passed it by rectum three days later, without suffering any inconvenience.

FIFTY-SEVENTH MEETING OF GERMAN NATURALISTS AND PHYSICIANS,

(Special Report for THE MEDICAL RECORD.)

A LARGE number of scientists and physicians from all parts of Germany attended the fifty-seventh annual meeting of the Association, at Magdeburg. They were greeted at the opening session by DR. GAEHDE, who delivered an eloquent

ADDRESS OF WELCOME.

He reviewed briefly the history of the Association, which had been the parent of many other illustrious bodies, such as the Surgical Congress, the Congress for Internal Medicine, the Public Health Association, etc., and had been the model and exciting cause of many of the existing international congresses. But while, the speaker continued, this Association might indeed be proud of her children, yet it should be remembered that there was danger to her own strength in so many childbirths. He counselled his hearers therefore to stand by their old mother and see that she was not injured by the rivalry of her progeny.

THE SECOND ADDRESS

was by PROFESSOR HOCHHEIM, who recalled the scientific glories of Magdeburg, and dwelt upon the appropriateness of its selection as a meeting-place for German naturalists. The first medical paper was by DR. ROSENBACH, of Göttingen, and was upon the

RELATION OF MICRO-ORGANISMS TO WOUND INFECTION.

The paper was a most interesting one, but was chiefly historical and critical in character, and contained little that is not already known upon this subject.

The next paper of interest to physicians was by DR. SCHWARTZ upon the

RELATION OF HYGIENE TO PRACTICAL MEDICINE.

In spite of the great advances made in recent years in the study of public health and of the actual results already obtained, there yet remained much, very much, to do. Hygienists should not think of rest until the last dark and unventilated bed-chamber had been destroyed, the poor man's table had been covered with nourishing and unadulterated food, and the modern scourge of brandy had been driven back. Unfortunately but little assistance was obtained from the people themselves; it was necessary in many instances to force them to be clean. The practising physician could aid the hygienist greatly by seeking, whenever possible, to impress upon his patients the necessity of light, ventilation, and personal cleanliness.

The general session was then closed, and the scientific labors of the members were continued in the several sections.

SECTION FOR INTERNAL MEDICINE.

PROFESSOR SEELIGMÜLLER, of Halle, presented a communication upon

CARDIAC DEBILITY.

The author pictured the group of symptoms, usually called cardiac neurasthenia, as follows: After a period of cardiac disturbance, palpitation, pain in the precordial region, there ensues a condition of general weakness, expressed by fatigue after slight exertion, insomnia, forgetfulness and distraction, and a depression of spirits. At the same time, despite a good appetite, sometimes even boulimia, there is a falling away in nutrition, the extremities are cold, and there is at times a feeling of formication. In the absence of any organic changes, the author was inclined to refer these symptoms to anomalies of innervation, especially as they occurred most frequently after psychical disturbances, as prolonged sexual excitement, severe mental labor, combined with broken rest, etc. Rest, warm baths, good nourishing food, sea or mountain air, and quinine in small doses often exerted a favorable effect.

DR. WAGNER spoke of the difficulty of diagnosis at the first examination in these cases. In all heart affections where there were no apparent physical disturbances, especially in those of advanced years, disease of the coronary arteries should be suspected. The speaker had seen cases similar to those described by the author of the paper in women who had borne many children or who suffered from certain forms of uterine disease. This condition was caused in those cases by an overloading of the abdominal organs with blood, and was much benefited by wearing an abdominal supporter.

PROFESSOR STRÜMPELL, of Leipzig, then followed with a paper on

ACUTE ENCEPHALITIS OF CHILDHOOD.

This affection resembles in nearly every particular infantile spinal paralysis. It occurs with greatest frequency during the first and second years of life, seldom later. There is usually an initial stage of fever, vomiting, and convulsions, followed after a varying period by paralysis. This is usually nearly complete on one side of the body. It diminishes after a time, but usually leaves more or less impairment of motion and of growth in the parts. Sometimes the affection is followed by motor irritative symptoms, such as epilepsy or athetosis, or by impairment of the intellect or power of speech. The sensibility of the paralyzed side is unaffected. The disease is located in the cortical substance. The speaker thought it possible that poliencephalitis and poliomyelitis might be essentially the same conditions, the disease being located now in the gray substance of the cord and again in the corresponding portion of the encephalon. In answer to a point raised in the discussion of this paper, the author said that he made a diagnosis of acute encephalitis only in those cases in which there was an acute initial stage followed by a stationary cerebral paralysis.

PROFESSOR EBSTEIN, of Göttingen, followed with a communication on

THE TREATMENT OF TYPHOID FEVER.

His conclusions were based upon an experience with upward of two hundred and fifty cases seen within a period of seven and a half years, and were as follows: 1. The so-called abortive treatment with calomel is useful, and therefore to be recommended. 2. A treatment based upon etiological grounds is impracticable, and the management of the disease must be regulated by a careful study of all the symptoms. The diet requires special attention. 3. The struggle to reduce a long-continued high temperature is necessary only when there are threatening symptoms on the side of the heart or nervous system or both, or when the fever itself reaches a dangerous height. 4. The author's experience led him to assert that the best results were obtained when reliance was not placed exclusively upon cold baths or any other so-called strictly antipyretic method. As regards antipyresis from drugs he had met with success in the use of salicylate of soda.

PROFESSOR KOEBNER, of Berlin, read a paper on the

THERAPEUTIC USE OF THE LOCAL ANTISYPHILITIC ACTION OF MERCURY.

The author related a number of instances showing the value of mercury locally applied, either endermically or hypodermically, in syphilitic affections. In the former case the mercury acted by direct absorption through the skin, and not through the inhalation of mercurial vapor, as was supposed by Kirchgässer. The speaker urged a more general employment of the local or regional application of the drug in connection with its internal administration. Whenever, after the general treatment of syphilis, there remain any indurations either of the primary sore, of the neighboring glands, or of any of the tissues,

we must seek to cure them by the local application of mercury. In this way we get rid of future centres of infection. Thus the occipital and cervical mastoid glands, which are usually passed by, should be treated for a long time by mercury endermically, the applications being interrupted from time to time in order to obviate the liability to inflammation of the skin and consequent impediment to absorption. Of course in such cases it must first be determined that the enlarged glands are not due to some local irritation within their lymphatic district, as for example when the glands of the neck are enlarged by reason of ulcerations in the posterior nasal region. The author, after trying various preparations, found that the most effectual as well as the least irritating was freshly prepared ointment of the gray oxide.

Dr. Anfrecht, of Magdeburg, read a paper of considerable length upon

CROUP AND DIPHTHERIA.

He regarded these two affections as absolutely identical. The bacteria were the same in either case and the anatomical differences were only apparent. In croup the membrane is separated entire and expectorated in the form of a tube, while in the faucial affection this does not happen. In diphtheria the mucous membrane is sometimes the seat of ulcers, but this, the speaker maintained, is the result of local treatment. It has been stated that the membrane in the pharynx could be removed only by force, while that in the larynx often became loosened spontaneously, but Dr. Anfrecht said that the mistake had been made of comparing the disease in the two parts at different stages of its progress. The pathological process begins in an exudation of fibrin from the blood-vessels of the mucous membrane excited by the presence of the bacteria. This fibrin is poured out between and upon the epithelial cells, and the strength of the attachment of the false membrane is dependent upon the depth to which the fibrin has penetrated the epithelium into the mucosa. The author did not believe that any advantage was to be derived from a local treatment of the disease. In the Magdeburg Hospital during the past four years two hundred and twenty-five cases of diphtheria had been treated, and but one death had occurred, and that was in a case in which a local treatment had been pursued. Cold compresses were applied to the throat and a gargle of chlorate of potassium was used. In children who could not gargle, small doses of the drug were given internally.

Some discussion followed, in which the author's views were in general subscribed to. The discussion was participated in by Drs. Schwalbe, Rindfleisch, and Rosenbach.

Professor Ackermann then read a paper on

CIRRHOSIS OF THE LIVER.

What is usually understood by cirrhosis of the liver, the interstitial hyperplasia of the connective tissue, is, strictly speaking, not the morbid process, but rather the expression of a secondary salutary process. The primary process is nothing else than a necrosis of the liver-cells induced by the presence of some poisonous substance (alcohol, phosphorus, and sometimes, also, it would seem, micro-organisms), which necrosis seems to be accompanied always by a deposit of fat in the cells. The cells are destroyed, and then follows a new formation of connective tissue proceeding from the interlobular substance. This is not a true inflammation, as there is no hyperæmia nor exudation of white corpuscles from the blood-vessels. There is, however, from the beginning a new growth of capillary vessels. But the interstitial new growth is not confined to a development of the connective tissue and blood-vessels, but embraces, also, the biliary vessels. This is a conservative measure, for otherwise the excretion of bile would be so greatly impeded as to destroy the life of the patient. The existence of these enlarged blood- and bile-vessels speaks against the view that the atrophy of the organ is due to a contraction of the newly-formed connective tissue. The atrophy is really due to an excess of cell-destruction over the new production of interstitial tissue. When, however, the new formation is in excess we find hypertrophy of the liver, a condition which is very common, especially at the commencement of the disease. There is another affection, probably identical with what has been called *cirrhosis glabra*, in which there is hypertrophy of the organ due to a diffuse hyperplasia of the inter- and intra-cellular connective tissue. This, however, has nothing in common with ordinary cirrhosis of the liver. There is no new formation of blood-vessels, but the old vessels remain normal and potent, and there is in consequence no ascites. The liver remains enlarged throughout the whole course of the disease, and the cells become atrophied from pressure of the surrounding connective tissue and not from a primary degenerative process.

After some discussion on this paper, Dr. Jürgens, of Berlin, presented a communication upon the

ANATOMICAL CHANGES IN ADDISON'S DISEASE.

The true seat of the disease lies, the speaker said, in the splanchnic nerve-trunks. The degeneration of these nerves may occur as a protopathic affection. In such cases there is a simple degeneration of the supra-renal capsules without any inflammatory manifestations in these or the neighboring organs. A deuteropathic disease of the splanchnic nerve following a primary affection of the supra-renal capsules or pancreas, is of much more frequent occurrence. But in all cases of disease of the supra-renal capsules, or of the pancreas, in which there is no bronzing of the skin, the splanchnic nerve-trunks are found intact.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 12, 1884.

R. E. Van Gieson, M.D., Vice-President, in the Chair.

PYELO-NEPHRITIS—REMOVAL OF THE KIDNEY BY ABDOMINAL SECTION.

Dr. H. C. Coe presented a specimen with the following history: The patient entered the Woman's Hospital two months ago with a tumor about the size of the fœtal head in the right iliac region, and rather movable. The tumor would disappear at intervals, and just previous to its disappearance the patient would pass large quantities of urine. No clue to the character of the disease was given by the examination of the urine. An exploratory incision was made, and hydronephrosis encountered, and the sac was removed. The patient developed peritonitis and died on the eighth day. After the operation there was never more than a slight trace of albumen and a few casts in the urine.

At the autopsy it was found that the stump had been secured, but the ureter had slipped and was blocked up with a clot, and some of the veins had also retracted beneath the peritoneum, giving rise to slight hemorrhage. The opposite kidney was not especially abnormal.

The particular point of interest in the case was that two days before death the woman had begun to menstruate, and the picture of the pelvic organs was very interesting. The uterus was retroflected, and all the pelvic organs were very much engorged with blood. The fimbriated extremities of the Fallopian tubes resembled dilated veins. The uterus was congested, and was like a sponge, blood flowing freely from all the sinuses. There was a corpus luteum in one of the ovaries.

On opening the uterus the mucous membrane was covered with a thin film, which could be raised with the forceps, and on examination, microscopically, it was found to be a layer of epithelial cells and blood under-

going fatty degeneration. The appearance seemed to confirm the theory of denudation of the mucous membrane in menstruation.

The ureter was perfectly normal, as also was the bladder. There was no mechanical obstruction between the kidney and the meatus urinarius, and the only explanation which he was able to give concerning the cause of the hydronephrosis was that there was merely a valve-like fold at the ureter as it opened into the cyst.

An interesting question arose; namely, Was there any uræmic element in the case? Twelve hours preceding death the patient passed only about two ounces of urine, which had a specific gravity of 1.020, exhibited a trace of albumen and a few casts, but no blood.

Dr. Peabody thought that too much stress was laid upon urea as a cause of uræmia, for the condition known as uræmia had been proven to be independent of any retained urea in the economy. He thought it had been shown that more urea can be injected into the veins of a dog than any human being can retain in any process of disease of the kidneys, and without producing any such symptoms as are passed under the name of uræmia. He did not think that urea had anything to do with uræmia.

Dr. Seguin remarked that he had been of the same opinion as Dr. Peabody, but Gréhant and Quinquand communicated to the *Academie des Sciences*, on August 25, 1884, the results of recent experiments in which they produced artificial uræmia by the hypodermic injection of urea in animals. Perhaps, therefore, the question had not yet been entirely settled.

Dr. Wendt thought that probably Dr. Peabody went too far when he said urea plays no rôle at all in the production of uræmia. He thought that the retention of urea was certainly one of the factors in the production of uræmia, although it might not be the only one.

Dr. Peabody said that one of the strong points in favor of the theory which he had mentioned was the fact that urea is excreted in large quantities by the mucous membrane of the intestines. It had been shown that by tying the ureters in roosters the urea, being unable to make its exit through the ureters, is found in large quantities upon the mucous membrane of the alimentary canal, and the conclusions to which he alluded were based upon experiments of this character. It would seem to be irrational, therefore, that urea should not find its way out of the human economy in the same way when it can do so in other animals, and that it can do so in other animals has been proven without doubt.

ANÆSTHESIA OF THE LEFT TRIGEMINUS, WITH SO-CALLED TROPHIC ULCERATION OF THE HELIX.

Dr. Seguin presented a patient, a man forty years of age, with the following history: He had had partial anæsthesia of the left trigeminus, left occipitalis major and minor nerves, of left superficial cervical plexus, and of left ulnar and median distribution for a year. The external ear is almost totally insensible. A few weeks ago a small "blister" appeared on the left external ear, in the lower third of the fossa of the helix. This has become an ulcer, which my colleague at the Manhattan Eye and Ear Hospital, Dr. Pomeroy (by whose courtesy he had seen the case) designated perichrondritis and chrondritis with perforation. There are no signs of ordinary hæmatoma. Under a dressing with bichloride of mercury lotion the ulcerative process has been arrested and repair is progressing. The only other symptom presented by the patient is paralysis of the left vocal cord, dating back six years to an attack of hoarseness. The man had never had syphilis, and the pathology of his anæsthesia (which certainly is not hysterical hemi-anæsthesia) was, he confessed, quite obscure. From the absence of neuralgia he was disposed to exclude disease of the trunk of the trigeminus or of the Gasserian ganglia. The ulcerations of the cornea (and phthisis bulbi) coexisting with trigeminal anæsthesia are well known, though rare. To his present knowledge this case was unique.

It has been claimed that the ulcerative keratitis of trigeminal anæsthesia, and the peripheral ulcerations after sections of nerve-trunks were active "trophic processes," the direct result of injury to "trophic" nerve-fibres contained within the affected nerve-trunks. The experiments of von Gudden and of Snelling have shown this theory to be untenable as regards the trigeminus. These experimenters found that by protecting the cornea (Gudden by artificial ankylo-blepharon, Snelling by sewing a rabbit's ear over the eye) there might be complete anæsthesia of the trigeminus with a perfectly clear, healthy eyeball. Long before them, however, Brown-Séquard had demonstrated that a guinea-pig's foot might be kept indefinitely healthy after section of the sciatic, by care and cleanliness. The conclusion reached by these physiologists, and the view now held by most neurologists was, that the keratitis or ulcerations of the foot was traumatic and infectious, the anæsthesia acting only as a predisposing cause by allowing injury, and by (in the case of the cornea) preventing the normal reflex protecting movements.

"In the case before us I believe that the ulceration was caused by scratching and subsequent sepsis of a little spot on the helix, the analgesia rendering the initial injury and subsequent extension of disease easy and rapid. In other words, had this anæsthetic ear been fully protected from injury and bacteria it would have remained sound. The healing under antiseptic dressing and protection, while the analgesia persists, is a proof of this view. Let me add that I know of one fact in experimental pathology somewhat analogous to this case. Years ago Brown-Séquard showed that after wounding one of the restiform bodies of the medulla in guinea-pigs the external ear on the same side often showed gangrenous ulceration at the tip and edges. May it not be that the wound in the medulla extended deeper than intended by the experimenters, and injured the ascending root of the trigeminus, thus causing anæsthesia of the affected ear?"

Dr. Levi thought it was not absolutely necessary that injury should always occur in order that ulceration should exist, because when the nervous supply is interfered with the normal power of repair is diminished. He did not think it was ever pretended that by doing away with the nervous supply of a part it would necessarily die, although it had much less blood to produce that reparative process which is going on in healthy parts. He would like to ask Dr. Seguin whether or not this was a case of ulceration due to interference with the nervous supply of the part.

Dr. Seguin replied that the anæsthesia acted indirectly as a predisposing cause only; that in the anæsthetic condition injury occurred more easily because of the insensibility of the patient to traumatic influences?

INGUINAL KIDNEY SIMULATING HERNIA.

Dr. E. C. Wendt presented a specimen of inguinal kidney removed from the body of a woman who had died of various senile disorders at the age of eighty-six. On admission to the St. Francis Hospital she affirmed positively that she had never known serious illness of any kind. She had for a number of years, how many she could not say, worn a truss for a supposed inguinal hernia. She died soon after admission to the hospital.

At the autopsy the right kidney was found connected by a firm band with the uterus, and was also situated in the inguinal canal, the portion protruding externally being that which had been mistaken for a hernia. It was evidently a congenital condition, and the kidney had no visible pelvis. The ureter was very much shortened. The kidney on the opposite side showed no special change. The renal artery in the inguinal kidney did not spring from the abdominal aorta; it probably arose from the iliac artery. There was no suprarenal capsule connected with the kidney removed from the inguinal ring, although it might be that one existed above.

ENDARTERITIS OBLITERANS.

Dr. Peabody presented a part of the circle of Willis, showing chiefly the basilar artery, together with some of the smaller arteries from the pia mater, removed from the body of a man, thirty-eight years of age, who died with peculiar symptoms. He was brought into the New York Hospital November 1st, unable to speak. He was bright and intelligent, and there was no paralysis of motion or sensation detected at the time of admission. There was exaggerated patellar reflex on the right side. The aphasia was distinctly ataxic, and at the same time the patient was unable to move the tongue. On the following morning there was complete right hemiplegia, the patient soon became unable to swallow, was nourished artificially, developed a rise of temperature in the evening after two days, and on the fourth day he had a succession of attacks of pulmonary œdema, in one of which he died. The urine was normal. The pulse and respiration were normal at the beginning, but toward the end they increased in frequency. At the time of death the temperature was 108° F.

At the autopsy it was found that the lumen of the vessels at the base of the brain, especially that of the basilar artery, was very much interfered with; that it was due to a growth in the interior of the vessels, and exhibited the lesion of arteritis obliterans. Dr. Peabody exhibited microscopical sections. There was a small spot of softening in the left corpora striatum and internal capsule, and the blood-vessels in these regions, upon both sides, were distinctly calcareous. The softening was localized. The convolutions were all normal. The other organs throughout the body were substantially normal, except old fibrous indurations at the apex of each lung, and in one kidney there were two small, old abscesses.

Dr. Seguin asked concerning the condition of the left Sylvian artery.

Dr. Peabody remarked that he examined this artery with special care, and there was apparently nothing wrong with reference to it.

ANEURISM OF THE ARCH OF THE AORTA—LOBAR PNEUMONIA.

Dr. Beverley Robinson presented specimens accompanied by the following history, furnished by Dr. J. M. Mabbott, of St. Luke's Hospital: Nicholas B——, fifty-three years of age, married, native of Switzerland, was admitted to the hospital July 14, 1884. The patient's family history was negative. He had a venereal sore in 1854, not followed by suppurating bubo. An eruption appeared upon the legs a few months afterward. In 1857 he had acute rheumatism, but suffered from no cardiac symptoms following the attack. He had pleurisy on the right side one year ago. He has indulged freely in alcoholics and tobacco. During his stay in the hospital the patient presented symptoms of aneurism of the arch of the aorta, which gave rise to marked difficulty in inspiration and expiration, but no other evident symptoms, so far as the pulse was concerned, and no paralysis of the vocal cords. On the evening of October 30th the patient had a slight chill, followed by excessive dyspnœa and very severe pain in the right side. On the following morning his temperature was 103.5° F., pulse 126, and the pain and dyspnœa continued. The breathing was laborious and the respirations were not increased in frequency. The patient died November 2d.

At the autopsy a few old adhesions were found over the apex of the left lung. The middle lobe of the right lung was in a state of red hepatization, and the pleura covering it had a large amount of recent fibrin upon its surface. The upper and the lower lobes of the right lung, and the whole left lung, were in a condition of emphysema.

The heart was of normal size, the valves competent, the muscular tissue of good consistence. The aorta was markedly atheromatous, especially the ascending portion of the arch, where was a large aneurismal sac, arising from the arch just at the origin of the right innominate artery, extending upward and forward, and pressing against and becoming adherent to the sternum. It was as large as a man's fist, and contained recent clots. There was a second aneurismal sac, extending backward and somewhat to the left, arising just below the origin of the left carotid and subclavian arteries. The innominate, left common carotid, and left subclavian arteries were also atheromatous.

The kidneys and liver were congested, the spleen was soft and friable. The stomach and intestines were congested.

From a clinical point of view the case was interesting because of the absence of the radial pulse, the presence of two considerable aneurismal sacs, the absence of any disturbance of the larynx although the trachea was considerably compressed. Although there was a distinct chill with complaint of pain in the right side nothing was found on physical examination which enabled him to say that pneumonia or pleurisy existed. There was no sputum. The primary cause of death was aneurism; the secondary, pneumonia.

Under such circumstances Dr. Robinson thought that one could only presume the existence of the pneumonic condition, without being able to say positively that it existed.

TUBERCULAR MENINGITIS—OLD CATARRHAL PHTHISIS.

Dr. Van Gieson presented specimens which illustrated in a remarkable degree the conservative and curative processes of nature, unaided by the physician's skill or art. They also illustrated the aphorism of Niemeyer, that the greatest danger to which phthisical subjects are placed is that of becoming tubercular. They were removed from the body of a man, fifty years of age, whom he first saw November 5th. At that time the patient was somewhat actively delirious, without special elevation of temperature. On physical examination there was found evidence of solidification of the apex of the right lung, and he was somewhat inclined to take the view that it was a case of low-grade pneumonia. At the next visit the delirium had increased, and Dr. Van Gieson succeeded in obtaining a history, which was that the patient had had vomiting more or less for several days, intense headache, and had had a staggering gait. The man became violent, and he was sent to St. Catherine's Hospital on Thursday, and died on the following Monday night. During his stay in the hospital there was no elevation of temperature. He died in a state of partial coma, varied with active delirium. At the autopsy the brain presented the typical appearances found in tubercular meningitis. After removing the lungs, the right was found entirely adherent posteriorly as far down as the diaphragm, and was so firmly attached to the diaphragm that it was necessary to cut off a portion of that muscle before it could be removed. The left lung was adherent to the chest-wall by a slight band posteriorly. The upper portion of the right lung was filled with calcified material, and the left lung also contained more or less of calcified nodules. The patient had not had a sick day, nor lost a day's work, during the last thirteen years. Dr. Van Gieson regarded it as probable that during the middle period of this man's life he had what had been called catarrhal phthisis, from which he had recovered. He would ask if it was common to find, post-mortem, such extensive evidence of previously existing destructive disease of the lungs?

Dr. Peabody replied that he had not had an opportunity to examine the specimens presented by Dr. Van Gieson, but he did not think it was common to find extensive evidence of phthisis which had been latent for years. To find occasional nodules was not uncommon, and it was sufficiently common also to be unworthy of special consideration to find extensive pleuritic adhesions.

The Society then went into executive session.

Correspondence.

TRACHEOTOMY IN CROUP AND DIPHTHERIA.

To the Editor of The Medical Record.

Sir: In The Medical Record of December 6th I am pleased to find an interesting communication from Dr. S. S. Jones, criticising my paper on "Tracheotomy in Croup and Diphtheria." Permit me a word in reply.

Dr. Jones says that I "advocate an early operation, giving as a basis for my argument the clinical histories of three cases." Herein he entirely misapprehends the purport of my paper. The latter was written after hearing the essay of Dr. Winters, which is so replete with historical and statistical information that I would have deemed it absurd to *base* any argument by which I desired to second his views, on *statistical* evidence from my own personal experience.

Those who have done me the honor to read my contributions to medical literature are aware of the fact that I am in the habit of fortifying my views by large and unassailable statistical data obtained from all available sources. The latter having (in this case) been already furnished by Dr. Winters, I desired only to aid in combating the unreasonable prejudice which seems to exist against tracheotomy among physicians as well as laymen. With this view I cited three recent cases, as an *illustration* that "one successful tracheotomy (in this instance performed by Dr. A. Jacobi) would do more to neutralize groundless apprehension than all the statistics," etc.

As "two of these cases were circumstanced precisely alike, being of the same age and in the same social grade," and occurring in the same epidemic, I utilized them to contrast the result of an early operation with that of a late one. If I had wished to enter into details I might have stated that in this epidemic of laryngeal diphtheria, which swept away quite a number of children (I have not yet obtained the exact figures from the attendants, being myself only called in council in a few cases), *the only recovery was in the case I cited as being tracheotomized*, and I might have furnished other details, which I reserve for future discussion. It was not my intent to write an essay, but simply to arouse an interest in the discussion, and I am glad that this result has been attained.

Dr. Jones has also misunderstood my position with reference to an early operation. If he will read my paper carefully he will find that I say "it is the duty of the attendant to operate early in the first indication of *abiding* laryngeal stenosis." Cases may, as he says, appear "threatened by asphyxia and yet recover." It is for the attendant to decide whether the stenosis is *abiding* or only paroxysmal. I have myself watched a case of laryngeal stenosis an entire night, while instruments and table were in readiness for tracheotomy, which was found unnecessary when the morning dawned.

Dr. Jones says: "I cannot but dissent from the conclusion of the author, because I believe that if tracheotomy were generally performed early in croup many children would be unnecessarily subjected to it, and *cures which would have been either spontaneous or the result of medical treatment attributed to it*" (italics mine).

To one who, like Dr. Jones, is "actuated in operating more by the desire to relieve the patient, if only temporarily, than inspired by any great hope of saving life," the fear that tracheotomy may get the credit of a cure without deserving it, may seem an insuperable objection to the operation. But if I mistake not the temper of most practitioners, such an argument would not be regarded a moment when a human life is to be saved. Nor would Dr. Jones' statement that deaths are sometimes attributable, "worst of all, to the accidental stopping of the tube," weigh against the operation, carefully done and watched over in the after-treatment.

It is just this prejudice against tracheotomy which has impaired its usefulness, and to dispel which Dr. Winters' paper and my brief contribution have been written. There exists no more baneful nor more universal error among medical men, especially when our experience is not large, than the habit of making deductions from that small experience for our own guidance. It would surely be far more rational and just to temper our egotism by utilizing as guides the published experience obtained by others from large clinical material—*plus* our own experience. Under such treatment Dr. Jones' seven tracheotomies with one successful result, would lead him to recognize that he is in error, when he regards his own experience in tracheotomy as compared with the results of non-operative management as unfavorable. Dr. J. Lewis Smith has told us that, according to his experience and observations, about *one in eight* recover by inhalation, which he regards as the best treatment. Now, Dr. Jones has had the good fortune to save *one in seven* tracheotomied cases, even when he treated the operation in a kind of "stepmotherly" manner. Hence he should be encouraged by this comparison to look with more favor upon the operation, especially if he will study *without prejudice*, the statistics, "from which it appeared that from twelve to thirty-nine per cent. had been saved by the operation, and, under improved methods of operating, it might be expected to save *one in three* by tracheotomy" (J. Lewis Smith). Indeed, this favorable result is nearly attained in the aggregate of the cases referred to in Dr. Jones' letter and my paper; for here we have *three recoveries in eleven cases* (Dr. Jones one, Dr. Jacobi one, and Dr. Baruch one). Dr. Jones recommends "equal parts of powdered alum and sulphur to be blown into the throat at the moment of deep inspiration as often as asphyxia threatens." This treatment will, I think, find little favor with practitioners. "The child," says Dr Jones, "*struggled through the next thirty-six hours*, expelling shreds of membrane after the insufflation at frequent intervals, until at length on *the fourth day*, the respiration, though *somewhat difficult*, was much deeper and freer" (italics mine). Aside from the apparent cruelty of this procedure, no physician bearing in mind the fact that in diphtheria there is great danger from heart-failure, would have the temerity to subject the little sufferer to the *struggle* incident to this suffocating process, "used, if used at all, freely and energetically."

One of the chief advantages of tracheotomy in laryngeal stenosis, and one which has not been sufficiently emphasized, is the tranquil condition of the patient resulting from the majority of operations. With proper care of the tube and skilled supervision of the after-management, the little sufferer is at once transposed from "a bed of thorns to a bed of roses," as it were. The natural (not carbonic oxide) sleep, the renewed facility of taking nutriment, medicines, and stimulants, the vitalizing influence of free ingress of oxygen to the lungs—all these conspire to change the whole aspect of the case. No statistics are required to demonstrate this fact; it is within the experience of most practitioners.

Let each one divest himself of all prejudice at this time, scan all the arguments and statistics brought forward in the discussion of last March, and in the present renewal, then add his own experience without fear and without favor. The result will be a triumphant vindication of the life-saving properties of tracheotomy, when performed as soon as *abiding* laryngeal stenosis is recognized, and carefully watched in the after-treatment.

Simon Baruch, M.D.

43 East Fifty-ninth Street, December 7, 1884.

The Most Powerful Antisuppurative, according to Trastour, is Lugol's solution, or iodide of calcium. He gives the former in doses of ʒ iij.–ʒ iv. daily.

SPINAL DISEASE AND SPINAL CURVATURE.[1]

By MEIGS CASE, M.D.,

LATE SURGEON FORTY-THIRD NEW YORK VOLUNTEERS; LATE PRESIDENT OTSEGO COUNTY, N.Y., MEDICAL SOCIETY.

In the production of diseases or deformities of the spine mechanical causes predominate. It is nearly safe to say that they are all due to some mechanical cause. Any undue shake, twist, or forcible flexion of the eighty articulations of the spine; any direct or indirect violence or contra-coup; any bruise or extravasation into the complicated bony or intervertebral tissues, any disturbance or dislocation upon each other of the seven distinct centres of ossification that compose each vertebra in the young, may be an original cause of disease or curvature.

The precise location of the injury, and the consecutive effect of the weight of the superincumbent parts, from which there is no escape without extension, determine the character and form of disintegration or deflexion which ensue by slow inflammatory processes superinduced by continual repetitions and aggravations of the original hurt. To this is added as the disease advances and pain is developed the well-known destructive influence of muscular spasm or unremitting vise-like compression, produced by nature's instinctive effort to limit motion and thus allay friction of the diseased joint. This effect is not unlike the process by which bedsores are produced by arrest of circulation.

Incessant and unvarying pressure, by its destructive strangulation of nutrient vessels, completes with abscess the disaster of Pott's disease.

The mechanical causes of lateral curvature are naturally those that impair muscular counterpoise. Any local debility or enforced unnatural attitude aided by gravitation may give rise to all the varieties and exaggerations of this deformity. "Any constant pressure on the spine will produce curvature," according to Von Swieten. A trifling deviation at the beginning, perfectly curable by a few weeks' treatment, becomes, when neglected, a serious calamity, "painfully embittering after life," "for of all the varieties of deformity none so greatly detract from the beauty of the human carriage as distortion of the spine."

It therefore follows that every aberration or injury to the spine should be considered worthy of minute attention and subjected to careful treatment at the earliest possible moment.

The unfortunate fact that not one case of spine disease in a thousand is detected and treated as such from the beginning is very discreditable.

Parents discover this and say: "The doctors cannot decide what is the difficulty." Mistaken treatments for malaria, rheumatism, gastrodynia, colic, indigestion, growing pains, and worms, usually employ very considerable time before the serious character and injurious possibilities of the prime injury are plainly diagnosticated by the occurrence of actual deformity.

This period of doubt and incertitude would be abolished with the deformity it perpetuates, if an acceptable, convenient, and ever-ready means of treatment of acknowledged efficacy and utility were at hand; but if the disease remains undetected and untreated until deformity is reached, a great opportunity has been lost, for prevention here, as elsewhere, is better than cure.

It is evident, however, that any treatment sufficiently well devised to relieve, modify, or benefit the most advanced stages of these diseases ought to cure, when early and properly applied in the forming stage.

This brings us to the consideration of the means of treatment in use by the application of some of the forms of so-called "rest."

Among these are "fixation" and "absolute immobility" splints, terms which sufficiently describe popular treatments by "braces" and "jackets."

The number and variety of these devices, all intended by lateral compression, or crutches resting on the hips, to support the weight of superincumbent parts, is appalling. Their production has become "a great American industry." Some of them like the "jury-mast," contain the merest suggestion of spinal extension, upon which alone valid claims to favor could rightfully be based, but accomplish it so imperfectly and indifferently, by means so disadvantageous and indirect, as to have compelled me to adopt a more simple and effective method by which "elastic extension" is furnished without compromising entire freedom of action.

My apparatus consists of a four-wheeled carriage, with parallel bars for the hands, surmounted by two upright spars and cross-piece, from which depends a powerful spiral spring, and below this a swivelled bar, carrying suitable soft leather suspensory rests to embrace the chin and occiput. The elevation is regulated by a screw, and can be increased as tolerance is manifested in the use of the apparatus and the patient gains in height.

In dorsal and lumbar curvature, a corset or waist suspension is added, arranged with large wood rings, through which the arms are passed, so as to avoid any of lifting the shoulders or limitation of their movements in any direction.

The patient can turn around and move freely to and fro, walking or running in the suspension at will, and a pleasing change of position is accomplished by an adjustable seat. Action or continual change of position is thus rendered not only possible, but agreeable and pleasurable.

The proper adjustment of the suspension is directed by the patients themselves.

The spring accompanies every movement and is strong enough to support the entire weight when required. Thus all restriction is practically done away with. I have found it useful in all cases where spinal extension is indicated, and those comprise nearly all spinal affections, not only Pott's disease and all of the forms of lateral curvature, but muscular debility and chronic fatigue of the erector muscles, with or without paraplegia or spinal irritation.

H. Heather Bigg,[1] the celebrated English orthopraxist, sufficiently illustrates the requirements of treatment in these cases when he deplores the fact that "every form of instrument with which I was aquainted before I designed these (a new brace with rubber attachments) limited or entirely suspended muscular motion."

He previously alludes to "*the necessity that appeared to exist for such an application of mechanical power to the treatment of spinal curvature as would admit of complete bodily freedom.*" In this we claim to have succeeded, for the apparatus not only does not impede but

[1] An address delivered before [illegible]dson County, N.J., Medical Society.

[1] H. H. Bigg: Orthopraxy, page 282. London, 1877.

greatly facilitates movement, and fortunately does not add weight to a patient already orerweighted by disease.

A plain reason why the traction is more efficient than any other is that it is not monotonous, but changes with every movement, from a few pounds to the entire weight.

The apparatus furnishes appropriately the most agreeable and beneficial "spinal exercise" for treatment of lateral curvature. It is only by suitable extension that the retraction and wasting of the spinal ligaments and muscles, the absorption of the vertebral tissue, the formation of antagonizing or compensatory curves, or the lateral horizontal movement known as "rotation" can be prevented or permanently corrected.

It is thus more "according to nature" than any form of straitjacket, brace, or "absolute immobility splint" with which I am acquainted. Observing a patient with Pott's disease you will notice that by trying to support the weight of the head on his hand, or leaning across his mother's lap, or sitting with both hands resting on the chair, or walking with a stiff and unnatural gait with both hands on his knees, he is constantly furnishing unmistakably the indications for treatment by extension.

The principal joints of the lower limbs are half bent, to prevent vertebral concussion, the projecting chin and elevated shoulders are held stiffly by rigid spasm of all the dorsal and intercostal muscles.

Movements are executed with automatic precision. Stooping is impossible in the ordinary manner and is accomplished by bending the hips, then the knees, then sliding awkwardly to the floor.

The muscular movements of the heart are directly interfered with by the unnatural spasmodic rigidity of the thoracic compression. It flutters like a bird in its cage, while the respiration, equally embarrassed, is short and grunting. Cyanosis and the peculiar facial expression are thus produced. It is suggestive that no child asks its nurse to compress its chest for temporary rest, or other reason, but if you tentatively lift the head by placing the "elastic extension" of your hands under the chin and occiput, a smile of grateful relief comes over the sufferer's face, and he says, "That feels good."

Now if you take the little patient at his word, and put him in this apparatus, you will find that he will indicate unmistakably its relief. He will breathe easier, the characteristic facial expression of the hunchback will disappear, and all bodily movements will be better performed. Soon his height will increase; and by pursuing a life of constant activity and exercise, a cure or a most gratifying improvement in vigor and form will take place.

What is "rest" for the spine? I define it as a complete reversal of the ordinary function of the spine by active extension.

A treatment by traction and free motion is thus directly indicated and is far more curative and beneficial to the spine itself than inaction or recumbency. A healthy *resistance* is imparted to the entire section, *effectually preventing abscess, and when it has occurred, greatly promoting resolution and the processes of repair.*

The injustice to sound articulations, which involves them in treatment and pseudo-anchylosis intended for *disease* is avoided.

If "rest" can be accomplished without interfering with the normal motion indispensably essential to the health of joints, so much the better. A joint deprived of motion is already diseased; condemned to inaction and loss of function; its "occupation gone," the conditions most favorable to abscess and disintegration are filled. The demand of the joints for motion is as incessant and insatiate as that of the lungs for air, or the heart for blood. "Immobility," "constant fixation," any form of "motionless restriction," or rigid extension is not rest.

The governing principle of this treatment is too well known in its application to analogous diseases of other joints to require any extended comment.

The researches of Henry G. Davis, whose little work on conservative surgery is one of the most original, suggestive, and instructive that the practical surgeon can place upon his table, were the first to show the universality of the great curative principle of "elastic extension" in the treatment of all diseased joints. He "was the first to point out, as an always present factor in their destruction, the existence of unremitting pressure as effected by contraction of the muscles passing over the joints causing constant forcible apposition of the surfaces within the joint." He gave to the world the principle of "elastic extension" and applied it indiscriminately to the spine, hip, knee, or ankle.

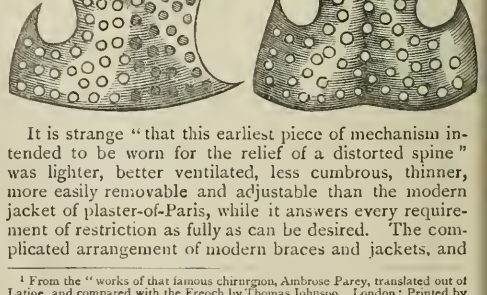
In my opinion this discovery entitles him to an eminence not less than that accorded to the discoverers of anæsthesia or vaccination. I fully believe that if his humane suggestions could be practically carried out, by the instant application of "elastic extension" in all appropriate cases, the hideous deformities arising from the causes under consideration would exhibit a curability at variance with the professional belief.

His apparatus for hip extension and suggestions for treatment have been almost universally adopted by the profession, relieving as they do all pain and spasm, and permitting free motion and recovery without deformity.

"Elastic extension and motion" have robbed this disease of most of its "terrors," as Davis said they would. The terrors of joint disease are pain and deformity.

"As a profession we are not sufficiently aware of the ultimate effect of continued suffering, of how many lives are lost that might have been saved had their surrondings been so arranged as to enable the patient to rest quietly, and to move free from every irritating cause; loss of sleep and rest, loss of appetite and nutrition; themselves sufficient to destroy life" (Davis).

In regard to the spine, he says: "The rational way to treat curvatures is to relieve the spine of the weight of the head and shoulders." But the application of the principle of "elastic extension" to the treatment of the diseases of the spine has never (as in the case of hip-joint disease) passed into general medical practice. The mechanician and specialist "hold the fort" with innumerable restrictive appliances fastened to the wretched bodies of these patients, illustrating all the evils of an ingenious but empirical system of mechanical therapeutics in all the varieties of worthless simplicity, cumbrous complexity, and injurious restriction; in fact, the treatment is practically unchanged since the Hippocrates of France, Ambrose Paré, in the sixteenth century, first suggested the "repoussé jacket" or body splint, beaten out of thin metal and carefully fitted by the skilful armourers of those days. Paré's breast and back plate below sufficiently illustrate the antiquity of restriction.[1]



It is strange "that this earliest piece of mechanism intended to be worn for the relief of a distorted spine" was lighter, better ventilated, less cumbrous, thinner, more easily removable and adjustable than the modern jacket of plaster-of-Paris, while it answers every requirement of restriction as fully as can be desired. The complicated arrangement of modern braces and jackets, and

[1] From the "works of that famous chirurgion, Ambrose Parey, translated out of Latine, and compared with the French by Thomas Johnson. London: Printed by E. C., and are sold by John Clarke, at Mercer's Chappell, in Cheapside Neare ye Great Conduit. 1665."

the constant changes required to keep these defective appliances in order, as well as their notorious inutility and danger, have compelled careful physicians who wish to retain the perfect confidence of families to abandon the "responsibility" of treatment of these cases by methods in vogue; but it has been readily sought and assumed by the specialist. An imperfect appliance always needs a good deal of engineering to supplement radical defects which a good apparatus does not require. Enumeration of the appliances restricting and encompassing the entire trunk in abortive attempts to give support to the spine is simply impossible. Their great number proves their inutility. But the most eminent recent authorities refer to them all as follows: "Mechanical contrivances are much vaunted, and are much employed. I confess, however, to having little faith in their value as curative agents. *They tend to cause atrophy of the muscles instead of strengthening them and thus to make the deformity a permanent one*" (Bryant).

"All the instruments at present so generally used, making direct lateral pressure on the convexity of the curves, must tend to increase the mischief" ("Lectures on the Pathology and Treatment of Lateral and other Forms of Curvature." Second edition, page 296. William Adams, London).

But the principle of "elastic extension" is just as immutable as it is curative. It is just as appropriate for one joint as it is for another, and by its thorough application, unembarrassed by restriction, not only all pain and soreness is relieved, but every indication for mechanical treatment is fulfilled, without peril or discomfort. Every indispensable condition and prerequisite to recovery is thus furnished in a direct and simple manner.

It is evident that if any improvement can be made, it must be in the directness by which the indications for treatment are fulfilled at the precise point where the effect is demanded without compromising normal action or function of neighboring parts.

The natural variability of the spine and the small size of its muscles as compared with those surrounding the hip-joint furnish conditions which render continuous unremitting extension far less imperative. Accordingly it has been demonstrated by careful trials that any supposed necessity for "night treatment" is obviated by daily active extension, and that improvement is more rapid when the natural sleep is not interfered with by any form of restriction or compression.

It is to be regretted that the attention which the magnitude of the misfortune of spine disease must have compelled from physicians in all ages has been so largely devoted to discussions of their supposed strumous or tubercular origin.

In the quest for a cause of the progressive ravages of maladies that contain in their *peculiar location* all the conditions of perennial disease in the constant attrition of the diseased surfaces or the cumulative action of its producing causes, the simple fact that no irritated or abraded joint surface can recover when subjected to constant spasm or pressure is forgotten in the wild and profitless search for an *original sin* of scrofula or tuberculosis.

Regarding so-called "Pott's disease" and so-called "hip disease" as identical in their causes, course, and general characteristics, I intend to supply, for similar reasons, an identical treatment purposing to answer the universal indication for elastic extension, appropriate to any stage, but especially intended for convenient and ready fulfilment of all requirements at the outset of the disease in accordance with scientific authority and sound pathology. There is, therefore, no longer any reason why every practitioner should not undertake the treatment of these cases as of any other lesions that come under observation in the ordinary routine of practice.

There is abundant reason why he should adopt such a course. It is only by immediate, persistent, and early attention to the requirements that deformity can be prohibited or its development arrested. Hence the necessity for recognizing, as a part of the general practitioner's duty, a thorough acquaintance with the early manifestations of these diseases, and the instant or earliest possible application of elastic extension by comfortable, efficient, and unobjectionable apparatus.

330 West Fifty-ninth Street, New York.

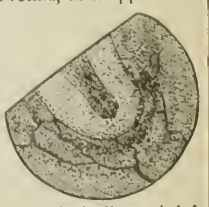
A CASE OF CYSTICERCUS IN THE VITREOUS.

By JAMES L. MINOR, M.D.,

PATHOLOGIST AND ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

During the past summer a patient consulted me at the New York Eye and Ear Infirmary for impaired vision, and I made the diagnosis of cysticercus in the vitreous. The extreme rarity of such cases—not a single authentic case, so far as I am aware, having been observed in America, although Graefe found eighty cases of cysticercus in the deeper tissues of the eye, among eighty thousand patients seen by him in Germany—caused at first much doubt in my mind; but the patient has been frequently and carefully observed since he was first seen, and I am now confident that the diagnosis was correct. And I am strengthened in my conclusion by the opinions of some of my *confrères* of the New York Ophthalmological Society—where the patient was shown—who have seen cases of cysticercus in the vitreous in the European clinics. The patient has repulsed all overtures pointing toward an operation for the removal of the entozoon, and I simply desire to place the case on record, with the hope that I may, at some future time, add the result of the operation thereto.

J. M——, aged sixty, male; seen in July, 1884, when the following notes were made: Ten days ago suffered great reduction in vision in the right eye, which has remained almost unchanged since. Vision in right eye $=\frac{3}{200}$, with excentric fixation, vision being possessed only in the temporal half of the visual field. The ophthalmoscope shows detachment of the retina throughout the temporal half of the fundus. Far forward in the supero-temporal quadrant, just behind the ciliary body, is a cyst, nearly transparent, of ovoid form, which contains (?) a cylindrical mass, apparently about one-half of an inch long, and one-eighth of an inch thick, that terminates in a free, somewhat pointed extremity. Just behind the tip, on either side, is a small black dot—hooklets—and behind these, a slight constriction—the neck—above which, after gradual enlargement, the tongue-like process reaches a point so far forward that it cannot be seen. Two parallel bands of delicate whitish tissue can be traced from the neck up to the point at which the whole object is lost to view. The upper part of the cyst is lost to view at the same point. The retina, as it approaches the cyst, assumes a wavy and wrinkled outline, and presents a mottled appearance, being interspersed with a number of small grayish spots (see figure). The obliquity of the eye necessary for a proper view is such as to make it difficult to distinguish between movements of the globe as a whole and individual movements of objects in its interior. Yet I have satisfied myself—as others have done—that the tongue-like process does possess individual movements. I have observed slight lengthening and shortening, a little lateral movement and tremulousness of the process. The position of the entozoon is such as to make it impossible to establish the exact relation of parts. The junction of the neck with the cyst-body cannot be seen, and the cyst is so transparent that it cannot be positively said whether the head and neck are contained therein, or whether they lie free in the vitreous, just in front of the cyst. I am in-



As seen by the *direct* method of examination.

clined to think that the latter is the case; for with the inverted image a marked parallax can be obtained, which not only shows considerable depth to the cyst-cavity, but that the head and neck lie well forward, in the anterior part of the cyst, or entirely in front of the cyst-wall.

21 Park Avenue.

A NEW METHOD OF MAKING INTRAVESICAL INJECTIONS, AND ITS VALUE IN THE TREATMENT OF CYSTITIS.

By C. W. ROBBINS, M.D.,

MARINETTE, WIS.]

Some three years ago, while practising in Milwaukee, I was called upon to treat a case of gonorrhœal cystitis in a young man. The case was aggravated and chronic; it had already existed seven weeks, and persisted for ten days longer in my hands without improvement with the usual remedies and rectal suppositories. The urine showed, on standing, a large amount of pus and mucus. In bulk the sediment was about one-fourth of the whole amount of urine in bottle (a four-ounce bottle full). Having no instrument for injecting the bladder, I decided to try a Davidson syringe and inject directly into the bladder per urethra. I first injected warm salt-water into my own bladder to test the feasibility of the plan. The fluid passed in nicely, halting only for two minutes at the sphincter. I then, the next time my patient came, injected his bladder with a solution (100° F.) of potassium chlorate and permanganic acid, injecting ten ounces of the fluid, *without causing my patient the slightest pain or discomfort.* The patient held the fluid about one minute, and the injection was repeated. In all, the bladder was thoroughly washed out four times at this sitting. The same treatment was practised the next day, and again on the following day, with the result of curing my patient entirely in the three days. At least all symptoms disappeared, and my patient had no relapse. About that time I removed from Milwaukee to the country and have only had two similar cases to treat since, in both of which the resulting cure was rapid and permanent; one case being cured in three sittings and the other in five sittings. The injection used is the one I have always used in gonorrhœa.

As I use it it is *entirely unirritating.* I use from one to three drachms of the permanganic acid to a half-saturated solution of potassium chlorate, ʒ xvj. The permanganic acid I made myself after the following formula:

℞. Potass. permanganate..... grs. ix.
Aqua destil..... ʒ j.
Solve et adde
Sulphuric acid, C.P..... ♏iij.

This is not strictly a permanganic acid solution, but it will do.

In this brief note I have not gone into details because I am not at all sure that the title at the head of my paper will hold good upon investigation.

If this method of treating cystitis is new and original, I ask of you to give this paper space in your columns, hoping that some of you New York surgeons will test the treatment thoroughly.

Micrococci of Pneumonia associated with Scarlet Fever and Diphtheria.—Dr. Lumbrosa concludes, from the examination of four cases, and culture experiments, that the micrococcus found in broncho-pneumonia occurring in scarlet fever, diphtheria, and croup, although identical in form with that of true pneumonia, is not biologically the same. He was never able to reproduce the disease from the pure cultures. He believes that in infectious diseases the pneumonia coccus has altered properties.—*Le Progrès Médicale*, October 18, 1884.

THE IMMUNITY OF THE NEGRO FROM TRACHOMA.

By BENJAMIN I. BALDWIN, M.D.,

EX-HOUSE SURGEON OF THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK; SURGEON TO THE MONTGOMERY EYE, EAR, AND THROAT INFIRMARY.

In the last issue of the *Archives of Ophthalmology* there was a good paper by Dr. S. M. Burnett on "The Frequency of Eye Diseases in the White and Colored Races of the United States." The susceptibility and insusceptibility of the negro race to certain diseases is well known in the South. I will not attempt to give a reason for this, nor could I do so in many instances. The principal point which Dr. Burnett makes is the immunity which the negro enjoys from trachoma, and my object is to add my experience to his on that subject. The city of Montgomery is the centre of the great cotton belt of Alabama, and the country which surrounds the city is low and flat, and the soil very rich. This peculiar kind of soil in the South is cultivated almost entirely by the negro, so that we have around us an immense negro population. During the past eighteen months I have treated four hundred and eighty cases of eye diseases among the negroes, and I have yet to find a genuine case of tenement-house trachoma among them. I have kept an accurate history of all my cases, both in private and dispensary practice, and I believe that my data are of some help to Dr. Burnett in establishing an interesting clinical fact. I have seen many cases of papular conjunctivitis due to the lack of proper treatment of ordinary "sore eyes," but this is easily accounted for, as the race is careless about such mild troubles, and medical attention is not easily obtained in remote rural districts in the South. I do not care to discuss the nice distinctions which some analytical writers impose upon us, but that there is a great difference, clinically, between tenement-house trachoma and papular or granular conjunctivitis, due to a mild, protracted inflammation of the conjunctiva, I think, will not be denied. Dr. Burnett says: "If it should turn out that the negro does not suffer from trachoma, even when the surrounding conditions are such as usually develop it in other races, we have a new element that must be taken into account in studying that most important eye affection." Ah! this an important point to look into. Has Dr. Burnett ever found the negro living in *large numbers* under the same conditions which develop trachoma among the poor white element of our large cities? I think here is the place we may go astray in our statistics, if we do not reason carefully. To my mind, the lack of trachoma among the large number of negroes treated by me is explained by the fact that they have been among a class who have had a bountiful supply of fresh air, abundant sunlight, and plenty of exercise. Given a constitution free from any taint, with these elements, together with sufficient and proper diet, I challenge the invasion of trachoma, come what may. My opinion is, and will be till some good argument convinces me that I am wrong, that in all trachoma there is to be found, as a fundamental cause, a dyscrasia. It is true that the negroes of the South are poor, and they are often found greatly crowded in their cabins; yet these cabins are so constructed that there is never a lack of ventilation. I do not contend that trachoma is *never* found in the negro, for I saw one case during my term of service at the Manhattan Eye and Ear Hospital, but I do say that they enjoy a wonderful immunity from it, and I will reiterate that I have yet to find a true case of trachoma among the negroes in my locality in the South.

Montgomery, Ala.

Hydrocele and Cysto-sarcoma Cured by Operation.—Dr. J. M. Adams, of Spencer, Wis., reports a case of a patient, æt. 38, suffering from an enormous hydrocele, the scrotum reaching below the knee. Twelve quarts of fluid were removed from the sac. Incisions were then made, and a tumor attached to testes and tunica, weighing 2¼ lbs., was removed. The patient made a good recovery.

TREATMENT OF CHRONIC HYDROCEPHALUS BY TAPPING—A SUCCESSFUL CASE.

By J. G. PALMER, M.D.,

OAKBOWERY, ALA.

I WISH to report a case of successful treatment of congenital hydrocephalus. The patient was a negro baby, seven months old. I was called to see the child in July last. I diagnosticated the case as one of congenital hydrocephalus, and told the parents that the only hope for cure was in tapping. To this they would not consent. The accumulation continued until the head reached the enormous size of twenty-six inches in circumference—the bones of the head having become very thin by reason of the pressure from within. There was a space of two inches between the bones. The eyes were turned up under the upper lids from pressure upon the brain.

In consultation with Drs. Garison and Spratling the importance of tapping was urged and the parents consented. A small hydrocele trocar was inserted at the posterior portion of the anterior fontanelle, the head having first been shaved at the place of insertion of the trocar.

The fluid flowed freely. About eight ounces were drawn off, the trocar withdrawn, and a piece of absorbent cotton placed over the place of puncture, and held in place by a piece of adhesive plaster. The bones of the head were pressed into position, and held in place by a tightly fitting bandage.

Next day bandage, plaster, and cotton were removed, and more fluid was allowed to drain off, though much had done so during the night by the plaster's coming off and the cotton being moved out of position. The fluid was allowed to drain off at intervals until all was removed.

The child was then put upon iodide of potash, which was kept up for several weeks. The eyes soon regained their normal position. The child nursed well and fattened rapidly. There were some febrile symptoms for several days after the operation, but they soon subsided.

The head is yet big from the large size of the bones, they being very thin. The bones seem to be rapidly uniting, and the child is still fattening and growing.

SUBSTITUTES FOR SAYRES' PLASTER-OF-PARIS JACKETS.

By J. W. KALES, M.D.,

FRANKLINVILLE, N. Y.

IN a recent number of THE MEDICAL RECORD Dr. S. W. Smith brings forward a substitute for plaster-of-Paris for the construction of spinal supports, and urges some objections to the use of Sayres' admirable and original apparatus. The writer having had considerable experience, and having used many kinds of material in the construction of spinal supports, fails to comprehend wherein lies the superiority of Dr. Smith's instrument. How it could have warded off the sad termination of Case I., or have produced less constriction of the chest-walls in Case II., as quoted by the doctor, is not quite clear, provided the surgeon had properly applied the plaster-of Paris splint.

The writer has in his possession a spinal support which was constructed four years ago, and exhibited at the July meeting of the Cayuga County Medical Society in 1880. This support is constructed of narrow strips of tin. It was built over a cast of plaster-of-Paris procured in the usual manner. Part of the strips of tin were placed vertically upon the cast, the remainder of them horizontally, and were soldered at the points of intersection. A wire was run around the edges of the splint, thus forming an almost exact counterpart of Dr. Smith's instrument.

This support is easily and cheaply constructed by any good tinsmith; is light, elastic, appears well on paper, looks well when exhibited before a medical society, and when lined with chamois and covered with some fine material, as silk and lace, up in front, pleases the eye of patient and friends. But having constructed several they have been abandoned. They are metal. The slightest imperfection soon acts like a nail that projects through the sole of a shoe, and it is very difficult to avoid such imperfections. The perspiration attacks the metal, and the oxide of iron attacks the clothing; the patient can remove the splint, and soon it is relegated to the garret. Such has been my experience with metal spinal supports.

If we are to use anything except plaster-of-Paris, we would suggest *leather*. Leather splints are easily constructed by first thoroughly soaking the leather in water and then stretching it over the plaster cast. When dry, remove it from the cast and apply it to the patient. Any imperfection can then be easily corrected. Having secured a *perfect* "fit," finish the support by perforating it to any required extent, line and cover it with any desirable material, lace it in front, attach jury-mast, head-rest, or other desirable attachment. In the writer's hands leather has proved very satisfactory. When the disease is located in the lumbar region the plaster-of-Paris splints do not work as satisfactorily as when the dorsal region is affected.

In one case where the lumbar region was seriously affected, and Sayres' jacket, after many trials, had proved inefficient, and where a splint constructed by one of New York's best instrument-makers completely failed to give adequate support, the writer applied a leather jacket. By extending the lower edge of the jacket over the crests of the ilia and down quite to the greater trochanters, the body of the pelvis formed a fixed point of support. This jacket has been worn for more than a year. The patient has steadily improved, and her friends confidently expect complete recovery.

OCTOBER 22, 1884.

Progress of Medical Science.

PROFESSOR FRERICHS ON DIABETES.—The comprehensive work of Frerichs on diabetes forms the most valuable recent contribution to the literature of the subject. A summary of the author's views is given in the *Centralblatt für die Medizinischen Wissenschaften*, No. 41, 1884. The author distinguishes three principal varieties of glycosuria. 1. Glycosuria after poisons, which constantly occurs after poisoning by curare, carbonic oxide, amyl-nitrite, ortho-nitro-phenyl-proprionic acid, and methyl-delphinin. It occasionally occurs after large quantities of morphia, chloral-hydrate, hydrocyanic acid, sulphuric acid, mercury, and alcohol. Glycosuria after infectious diseases is allied to the above; *e.g.*, cholera, anthrax, diphtheria, typhoid fever, scarlatina, and malaria. In the last-named disease it was only found once in several hundred cases. The appearance of a copper-reducing substance in the urine, observed by different authors after the introduction of various substances into the body, does not rest on the presence of sugar.

2. Glycosuria from digestive derangements. While, as a rule, in healthy persons the ingestion of large quantities of sugar does not cause glycosuria, exceptional cases occur, in which even small quantities have this result. Apart from this, glycosuria is found occasionally in connection with gastric catarrh, especially in those who inherit a gouty disposition. It chiefly occurs during the intervals of gouty attacks. Experiments on the introduction of sugar in cases of phosphorus-poisoning, cirrhosis of the liver, and portal obstruction, gave only negative results as to the presence of sugar in the urine.

3. Glycosuria from nervous derangement. This includes glycosuria after psychic excitation, neuralgia, cerebral disturbance, injuries of the head and spinal column, and, finally, cerebral hemorrhage and cerebro-spinal meningitis.

Diabetes mellitus is distinguished from glycosuria by the appearance of extensive derangements of the tissue-changes generally, which lead to general deterioration, to many local diseases, and usually to death. In

speaking of the results of diabetes, twelve cases of cure are given. It often passes into some other grave disease —nephritis, diabetes insipidus, arterial sclerosis, and their consequences. But death is far the most frequent result; and, of 250 fatal cases of the author's, 18 died from exhaustion, 34 from phthisis, 7 from pneumonia (4 of these with gangrene of the lungs), 8 from nephritis, 7 from carbuncle, and 9 from complications (6 of these from cancer). In all the other cases symptoms of cerebral paralysis appeared, in 10 from hemorrhage, in 2 from softening, in 3 from cerebro-spinal meningitis, and in the rest from coma without local alterations within the skull. Fifty-five cases are reported, together with their necropsies. Passing over the causes, immediate and predisposing, of diabetes, we come to the treatment, which is not so powerless as is often assumed, for the author has had cases under treatment for ten years up to eighteen years, and one case for twenty years. A proper mental and bodily diet is of the greatest importance, and muscular exercise carefully conducted is most beneficial. Milk was found unfavorable, especially Donkin's treatment by skimmed milk. Many alkaline waters were found very useful (Carlsbad, Neuenahr, Vichy), when taken at these places. Among narcotics, opium is important, as it often lessens thirst, urine, and sugar, while the body-weight increases. As to the experience, usually negative, of many so-called specifics, lactic acid had no result, and glycerine was harmful. Salicylic acid, salicylate of soda, and iodoform deserve further trial. All weakening influences and cutaneous irritants are to be avoided.

Infectious Osteomyelitis.—Dr. Rodet has found that when the micrococci of the pus in cases of osteomyelitis are injected into the venous system of rabbits, and therefore free to choose their seat, they show a marked preference for the bones, and more especially for those parts which are in process of active growth, where they set up a severe suppurative or necrotic form of osteitis analogous to osteomyelitis in man.

Sleep, Trance, and Death.—Occasionally we meet with instances in which death is simulated by some deep degree of stupor. The case of a laborer, living at Bridgewater, which was lately recorded, appears to have been one of this kind. The trance-like state developed quite suddenly, and was mistaken by the relatives for death. Some slight degree of warmth in the apparent corpse induced the clergyman in attendance to refuse burial in spite of the decided wish of the relatives that it should take place. After eight days, the signs of animation were re-established, and the subject of this singular experience slowly recovered. In all such cases, there is an element of mystery; and one cannot always decide how much of this is due to physiological or pathological conditions, or to some external agency. The *British Medical Journal*, in commenting upon the above case is led to make the following remarks: "The relationship between sleep, 'the cousin of death,' and death itself, is probably real as well as apparent. The distance which separates them is great, but there are intermediate connections, grades of dissolution as of development. Among these the similar states of trance and hibernation are worthy of special notice. For sleep and for trance one cause, the exhaustion chiefly of nervous matter, but more or less of every organ and tissue, is assignable. The hysterical stupor is the sleep of nerve-centres, worn out with the assault and conflict of stormy reflex action. Healthy sleep is the rest of physical elements wearied with the same strain applied more gradually. Cases have been recorded in which somnolence, continuing for days without cessation, has resembled trance in its duration, while preserving all the ordinary features of natural sleep. Various facts support us in associating the hibernation of animals with the same train of organic or functional changes as the other unconscious states which we have been considering. It comes like a habit; it has, one may say, annual return; its apparent cause is the oppression of external cold, and the animals it affects are mostly those which, from their bodily structure or habits, are subject to great periodic variations of temperature. Vital tissue is exhausted, and function is in part suspended, probably because the numbness of cold has taken hold upon the radicles of the outer circulation, and of that of the brain-surface which is connected with it by numerous anastomoses. In such a case anæmia would seem to be the cause of the winter sleep, as there is evidence to show that it is also the cause of that temporary starvation of brain which lulls without arresting its action, in the natural repose of each night. We may even regard the lethargy, ended by death, into which man falls when exposed to great cold, as a short and mortal hibernation. The same influence acts upon him as upon the bear or fish, but the power of its shock is greater on his finer and less accustomed senses than on their comparatively coarse organization. So, likewise, in other regions and forms of life, in the weariness, paralysis, atrophy, and gangrene of limbs, in the leafless hibernation of trees, and in their decay, beginning in the terminal twigs, the same teaching is evident, that vascular nutrition, in its periodic variations, is the parent of activity, and of rest, as its absence is of death."

Adenoma of the Liver in a Child Twenty Months Old.—A remarkable instance of this rare disease is found in the yearly report of the St. Joseph Children's Hospital in Vienna. A female child had suffered for three months with loss of appetite, emaciation, and swelling of the abdomen. The right side of the abdomen was occupied by a tumor reaching from the sixth rib to the iliac fossa, and on a line with the umbilicus from the linea alba to the vertebral column. Palpation showed elevations over the surface of the liver from the size of a horse-chestnut to that of a child's fist. They appeared soft when pressed against the resilient liver. There was also enlargement of the spleen, and the urine showed albumen. At the autopsy the liver was found to weigh over three pounds. Its surface was covered with knobby tumors of various sizes. Section showed the liver substance to be entirely replaced, with exception of its periphery, by a soft yellow mass sprinkled with numerous hemorrhagic points. It was separated from the resistant liver tissue by a thin capsule. Connective tissue septa ran through the mass, indicating that it had been formed from a number of confluent tumors. There were, besides this large mass, tumors from the size of a pea to that of a walnut scattered over the periphery. Some were so soft that they almost fluctuated. Careful microscopic examination showed the growth to be an atypical adenoma.—*Wiener Medizinische Wochenschrift*, No. 43, 1884.

Sudden Death in Labor and Childbed.—In the course of some remarks on the above subject, Dr. Lusk (*Journal of the American Medical Association*, October 18, 1884) observes that modern pathological investigation refers the phenomena of shock to a reflex paralysis of the vaso-motor, and especially of the splanchnic nerves, whereby the great mass of the blood is withdrawn from the surface, and collects in the large trunks of the cœliac, the mesenteric, and the renal veins. Hence the skin becomes cold and is devoid of color, save at the points where a bluish hue is imparted by the stagnant blood still lingering in the veins; the muscles deprived of blood become enfeebled; and the empty vessels of the brain explain the sluggish intelligence, the nausea, the vomiting and the indifference of the patient; finally, during the diastole, the heart, pale and contracted, receives but little blood, and the radial pulse fades to nothingness, because a corresponding small amount of fluid is propelled during the systole into the arterial vessels. From works on military surgery we learn that it is in the defeated army among homesick soldiers, at the close of a wearisome war after great exertions and deprivations, that shock is developed in its severest forms; that the finer the organization, the more readily the manifesta-

tions occur; that they are promoted by sudden losses of blood, and are in a special degree evoked by abdominal injuries. It certainly would be singular if similar conditions in childbed were not followed by corresponding results. After prolonged labor, the woman has her nervous system depressed by pain, starvation, and deprivation of sleep. The sudden emptying of the uterus is followed by a recession of blood to the venous trunks of the abdomen. Hemorrhage subsequent to parturition is followed by syncope, and the wonder is, not that the circulation should occasionally show the evidences of marked and even fatal disturbance, but that the nervous system, attacked from so many directions, should, as a rule, triumph over the adverse forces. In the old days of torture, shock often mercifully put an end to the victim's anguish. Women in childbirth are at times subjected to pain exceeding that of the rack and the thumb-screw. Now it is not sound pathology to ignore these facts, and to banish as unworthy of consideration a well-established pathological condition, simply because in the days of ignorance the terms exhaustion and shock were indiscriminately employed to explain a multitude of cases, which, with our present enlightenment, we know are due to the entrance of air into the circulation and to pulmonary embolism. As the nervous organization of women loses in powers of resistance as the penalty of a higher civilization and of artificial refinement, it becomes imperatively necessary for the physician to guard her from the dangers of excessive and too prolonged suffering. Especially I would raise my voice in warning against the current opinion that the length of the first stage of labor before the rupture of the membranes is a matter of indifference, a teaching which I believe has cost the lives of many women; in a few, death resulting from shock; in more, the exhausted condition in which the woman is left after childbirth rendering her an easy prey to the perils of the puerperal state.

Lipoma of the Arachnoid.—Dr. Braubach records a case of lipoma of the arachnoid of the cervical cord, extending to the point of exit of the fourth and fifth dorsal nerves. The cord was completely compressed and displaced to the left side. Below the region of compression there was descending degeneration of the pyramidal columns. Lipoma is very rare in this situation. Very few such cases have been recorded: one by Obré, one by Athol Johnson, one by Virchow, and a case of myolipoma by Gowers. The paraplegia of the lower limbs, their anæsthesia, the bladder weakness, the extreme contraction of both lower extremities, the increase of their tendon reflexes, need no comment. They depend partly on the compression of the cervico-dorsal cord, partly on the descending secondary degeneration of the lateral pyramidal tracts. Of greater interest is: 1. The fact that, in spite of the extreme compression and degeneration of the affected part of the cervico-dorsal cord, the conduction through it, at any rate of intense impressions of pain, was still retained. 2. The fact that, in spite of the great degeneration of the compressed parts, the roots on the right side that came off from these affected regions showed only very slight degeneration, the roots on the left side none. 3. The fact that the left upper extremity could be moved as in health, without any paralysis or contraction; while the right arm was paralyzed and extremely contracted. The latter symptom was, doubtless, due to the great amount of stretching of the right spinal roots, in consequence of the displacement of the cord to the left; and a permanent state of irritation was present throughout, which gave occasion to conic contraction of the right upper extremity.—*Archiv für Psychiatrie und Nervenkrankheiten.*

Bony Tumor of Brain.—The formation of true bony growths in the substance of the brain is believed to be of rare occurrence. It is possible that the apparent rarity is due to the infrequency of post mortem examinations of the cranial cavities of senile individuals. M. Witkowski has placed on record some of the particulars of an example of osseous tumor of the brain. The morbid growth was of the size of a walnut and occurred in the left hemisphere at its occipital part; it was quite independent of the pia mater or ependyma, being surrounded on all sides by brain matter. Its shape was like that of two pyramids set together at their bases; its surface was studded with a number of spicules, points, and folds, the last of which had a certain resemblance to the convolutions of the brain. The tumor was encased in a fibrous capsule, and presented many excavations filled with brownish or yellowish soft material, which was discovered on microscopical examination to be of the same structure as the marrow of bone. The fibrous capsule or periosteum of the tumor was composed of a dense connective tissue, calcified in parts. After the tumor had been decalcified by treatment with chromic and nitric acids, a hyaline ground substance was brought into existence, and lamellæ with bone corpuscles and Haversian canals were to be seen. The tumor was connected with the nervous substance by means of a delicate connective tissue strewed with amyloid corpuscles. There were no other osseous formations in any part of the central nervous system. The brain on the same side as the tumor was certainly more consistent than the right hemisphere, and the microscope exhibited an increase in the amount of connective tissue and stellate cells. The cerebral arteries were extensively thickened, and many small foci of the brain were in a state of softening. Some degree of internal and external hydrocephalus was found, and the ependyma was thickened. The brain was that of a man, aged seventy-nine years, who had never shown any symptoms of brain mischief during life. No accident could be assigned as the cause of the formation, which does not appear to have been an ordinary psammoma.—*London Lancet.*

Fatal Puerperal Infection in the Male.—Dr. Gandor reports this case in the *Revue de Médecine*, No. 9, 1884: A healthy man waited on his wife after her confinement. The woman died of puerperal septicæmia; the man developed a lymphangitis, preceded by chills, simultaneously, in one arm and leg. Soon all the symptoms of septicæmia appeared, and the patient rapidly sank, but rallied at length and made a tedious recovery. No wound or scratch of any kind had existed on his hand or foot to account for the origin of the lymphangitis. The author concluded, therefore, that the case was one of puerperal infection in the male. But he fails to explain in what manner the poison entered the system.

The Rose-colored Eruption not Characteristic of Typhoid Fever.—Dr. Juhel Rénoy relates in the *Archives Générales de Médecine* for October, 1884, two cases in which the typical rose-colored eruption was present, but in which there was no typhoid fever. In one case there was diarrhœa and fever, but the temperature curve was not that of typhoid, and at the autopsy no typhoid lesions were discoverable. The author concludes, therefore, that the presence of the rose-colored lenticular spots is not necessarily a sign of typhoid fever, since the eruption may occur in other febrile conditions. He suggests that possibly the eruption is due to some derangement of the cutaneous secretion.

A Point in the Differential Diagnosis of Variola and Varicella.—Dr. C. Bareggi withdrew a little of the fluid contents of variolous papules and pustules, and having made dry preparations in the ordinary way, and stained them with methylene blue, examined them under the microscope. He found large numbers of cocci, like those described by Klebs as characteristic of variola. The author was unable to find these microbes in papules or pustules of any other origin. They were absent in chicken pox, which fact would tell against the theory of the identity of varicella and variola, and might also be of value in the differential diagnosis of these two diseases.—*Centralblatt für Klinische Medicin.* No. 38, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

IS BLOOD-TRANSFUSION JUSTIFIABLE?

THE history of transfusion illustrates very forcibly the quick rise and fall in popularity of measures that do not rest on the sure basis of exact knowledge. It is within the memory of even the younger members of the medical profession that the transfusion of blood was regarded as one of the most important operations of modern surgery. Of scarcely a single other procedure was it said with such positive assurance that it constituted a grand life-saving triumph of the healing art. Yet to-day blood-transfusion is about to be relegated by unerring science to that still extending limbo of futile, if not harmful surgical interference. Professor v. Bergmann (London *Medical Record*, November 15, 1884) [1] has recently published a critical survey of the entire subject, but more particularly of the history of transfusion within the past decade. He starts out with some general observations concerning the commendable prevalence among physicians of habits of keen inquiry and searching investigation. The practical and fruit-bearing discoveries in modern medicine—especially as regards surgery—rest, he thinks, on the safe foundation of biological knowledge. This is as it should be. For whenever serious medical action does not conform, to what is really known, mistakes are sure to happen. Transfusion shows this very well. The author recalls the fact that centuries before physicians had any knowledge of the circulation of the blood, they tried by this bold measure to supply new vital fluid to the human body. According to the then prevalent idea, blood was equivalent to life and soul. Almost complete ignorance of the true function of blood made them attribute to that fluid all the mysterious manifestations of life.

It is not surprising, therefore, that we find in the seventeenth century not only individual physicians, but whole colleges and other learned bodies, seriously discussing the question whether a dog would get wool and horns after taking sheep's blood, and whether the disposition of sanguine or choleric persons could not be improved through the agency of gentle lamb's blood. Transfusion, it was also thought, could rejuvenate the aged. The introduction of the blood of one animal into the circulation of another was carried out in a variety of ways in the eighteenth century. Experience gained by this means showed that an animal nearly dead from loss of blood may be resuscitated, at least for the time being. But human transfusion was rarely done until about the second half of our century, when for a short period it suddenly rose to rather startling frequency. The operation was not confined to cases of sudden loss of blood. On the contrary it was often performed for all kinds of acute and chronic diseases. Patients were also bled to rid them of vitiated blood, and thus prepare them for the introduction of healthy fluid. Pulmonary and renal affections, dyspepsia, pyæmia, typhus, and cholera were treated by this method. No wonder, then, that grave mistakes, often fatal in their consequences, soon brought transfusion into discredit.

In 1859, its successful employment by Martin, of Berlin, in lying-in cases, once more revived its popularity, until about ten years ago it was looked upon as a universal panacea for the greatest variety of human ailments. But to-day this kind of unstinted enthusiasm has died a natural death. The more or less complicated apparatus of the transfusionist has been quite generally set aside. Perhaps it will soon be found only among the historical relics of a past era in medicine. Certain it is that we know much more about hæmatology than we did even a few years ago. And the mistakes that have been associated with the practice of transfusion are not likely to be again repeated.

In any great and sudden loss of blood, the arterial blood-pressure sinks so low that the movement of the blood is stopped. For a time the heart still works on, but ineffectually. It is like an empty pump, and ceases to draw and propel the column of blood. In the vascular system there is stagnation. Were the blood which the vessels still contain put again into motion, it would be sufficient to support life. Hence, as Kronecker first pointed out, in such cases a simple infusion of a saline solution is sufficient to save life. By this means the contents of the vascular system become increased in volume. This intensifies the intra-vascular pressure and re-establishes the working of the heart. Now we understand why in so many cases transfusion has saved life; why Lower's and Boyle's rudimentary experiments on dogs were successful. What was required was to fill the elastic tubes of the vascular system with fluid, not necessarily with blood.

Again, after considerable loss of blood the proportion of blood-corpuscles remaining in the blood becomes less and less, and for a variable time after the bleeding has ceased the diminution still goes on. Subsequently to the transfusion of a large quantity of blood the blood-corpuscles seem to be increased, but only for a time. Very soon their number diminishes, while the urea and alkaline elements of the urine, and the deepened color of the latter, betoken the ruin and disintegration of the blood and its corpuscles, which have been conducted in excess into the system.

The scientific study of the subject was much advanced by the counting of blood-corpuscles, but even more so by the results of the direct transfusion of animal blood. Supported by the apparently remarkable cures of Hasse, it quickly became a favorite measure. It seems scarcely credible how tenaciously physicians clung to this form of the operation even up to the close of the last decade.

After every transfusion with lamb's or dog's blood, the patients develop a series of morbid symptoms. First there is dyspnœa, followed by a feeling of being over-full, then

[1] Die Schicksale der Transfusion im letzten Decennium, Berlin, 1883.

sickness, and afterward sinking and uncontrollable stool-pressure. There are also headache, dizziness, and even short periods of unconsciousness. From ten minutes to an hour after the transfusion a chill will set in, often increasing to a violent shivering fit, then a stage of heat, with very high temperature. The hæmaglobinuria already mentioned is the direct result of the dissolution of red blood-corpuscles. We can scarcely understand to-day how many observers, in the face of such serious disturbances, could disregard the manifold dangers of transfusion with foreign blood. Their only apparently justifiable reason seems to have been, that one case after another of transfusion with lamb's blood seemed to be successful, or more correctly speaking, that the patients did not quite die.

The injurious effects of transfusion with foreign blood were attributed by Prevost and Dumas to the unequal size of the blood-corpuscles in different kinds of animals. As the blood-corpuscles of a sheep are smaller than those of man, they were considered harmless. To Ponfick must be given the credit of showing how erroneous this was. It is not the mechanism of the different-sized corpuscles that makes foreign blood injurious, but rather important chemical changes, which, when a certain quantity is transfused, makes the blood of a sheep a deadly poison to a dog, and *vice versa*. A complete answer has been given to the question as to what the harmfulness of foreign blood consists in. And henceforth, v. Bergmann thinks, this kind of transfusion should disappear from the stock of surgical remedies.

Long before Panum pressed upon the attention of physicians transfusion with defibrinated blood, Magendie had found by his experiments on animals that such blood caused decided disturbances, such as quick breathing, diarrhœa with tenesmus, and bloody effusions into the peritoneal, pericardial, and pleural sacs. Accordingly, he warned the profession against its use. It is easy to understand why physicians did not altogether follow him, because in direct transfusion there are the numerous risks of coagulation attending the use of syringes and canulæ. Virchow, in his work on "Thrombosis and Embolism," did not in connection with transfusion set forth these dangers, or else he under-estimated them. At the present moment, they form the principal objection to the only permissible form of blood-transfusion, namely, that with human blood intact.

The idea of plethora with increased blood-pressure after transfusion for the cure of certain diseases gave rise to the practice of bleeding the patient before the operation. Especially in treating septicæmia in this way, a large quantity of blood was taken from the patient in order that it might be replaced with new blood; doubtless a double injury to the patient, first by the blood-letting, and secondly by the transfusion. These operations nearly always proved fatal. But, at any rate, they showed the non-existence of increased blood-pressure as a cause of the fatal ending.

Whenever transfusion with blood has saved life, it has done so by starting a sluggish or stagnating blood-current to quicker motion, and not through any reviving respiratory action of the blood-corpuscles. It is owing to two things that transfusion has often passed off without danger, and has even been endured without much disturbance. The first is the small quantity of blood, usually not much exceeding one ounce, that was employed. With this they tried to cure phthisis, chlorosis, and chronic intestinal catarrh. The second is the power of resistance of the organism against the effects of the fibrine-ferment. If, however, transfusion carries with it grave dangers, we are forced to the conclusion that we are on the wrong track. All that can be effected by the operation can be effected by other and simpler means, namely, by infusing into the veins a solution of common salt. It has been established by numerous cases that, when transfusion of a solution of common salt is used it revives the patient and causes the heart to beat. It is conceivable that a patient may be revived by something injurious. But if it can be done by something that is harmless, we should welcome the latter. There is only one kind of blood-transfusion that can really be justified: the transfusion of blood from the artery of one man directly into the vein of another.

Experiments have been made to convey fluids to the blood by other means than transfusion. But they have proved barren of lasting benefits. Thus, when it became known that fluids are sometimes rapidly absorbed by the peritoneum, the attempt was made to replace transfusion by flooding the peritoneal cavity with defibrinated blood. The lymphatics seemed to eagerly absorb notable quantities of it. But hæmatic icterus resulted, and the urine soon showed the presence of uro-obilin. Intraperitoneal transfusion is, therefore, unjustifiable.

If we accept v. Bergmann's teaching, and certainly he makes out a strong case, it would seem that blood-transfusion is really a thing of the past. On the other hand, the introduction of some saline solution into a vascular system threatened with profound stagnation, would be a substitute that is free from the manifold dangers inseparable from the older method of transfusion.

THE ATTACK UPON DR. FORDYCE BARKER.

It is with the profoundest regret that we chronicle the proceedings of the New York Academy of Medicine of last week. The wanton attack upon the venerable President furnished an exhibition of impotent spite and stupid malevolence quite without parallel in the medical annals of this city. A distinguished physician, who has practised his profession blamelessly for thirty years, whose high qualities of character have drawn about him an ever-increasing troop of friends, whose professional attainments have won for him the most distinguished honors at home and abroad, who has been justly looked upon as one of the best types of American physicians, and who in his later years has, by self-sacrificing and assiduous efforts, raised the Academy of Medicine to be the foremost medical society of the country—this man is at last made the victim of a baseless charge that he has been a life-long hypocrite, that he is not legally a doctor! The infinite pettiness of mind which could trump up these accusations, so easily proved false, is quite past comprehension.

Neither can we understand how men, who have been posing as representatives of a high professional morality, should so blindly give the lie to their pretensions by devising and giving publicity to a contemptible slander

upon a brother physician; for it is not alone that the character of Dr. Barker was impudently assailed—that gentleman has been too long known and too widely honored to be harmed by the slander brought against him—but the profession itself has been injured by the publicity given to a disgraceful and unnecessary quarrel.

The medical profession at large will hear and judge who best represents the true standard of professional honor, Dr. Fordyce Barker or those who have again so wantonly fomented discord, excited bitterness of feeling, exposed our dissensions to the world, and maliciously attempted to injure a physician than whom no one more deserves to be honored at our hands.

THE THERAPEUTICAL VALUE OF ELECTRICITY.

Two papers of interest, by Dr. Hughes Bennett and Dr. W. E. Steavenson, respectively, were read at the last meeting of the British Medical Association. They treated of the somewhat hackneyed subject of electro-therapeutics, but the points made in them and the discussion which followed drew out some thoughts which deserve attention. They showed for one thing that in England as in this country the general practitioner knows very little about electricity, and does not trouble himself with it much in his daily practice. Further, Dr. Steavenson expressed the opinion that the cost of an electro-therapeutical "plant," the expense of keeping it in order, and the time occupied in applying electricity would in time throw a large part of electro-therapeutical work into the hands of specialists, or of electricians who would rank with cuppers and masseurs, doing just what was directed and no more.

Such an arrangement will be slow to occur in this country because, even if it were desirable, our sick population is too scattered to support "electricians," except in the large cities.

Nevertheless, there is unquestionably a tendency in this direction of electro-therapeutical specialization. Physicians in general practice, who have batteries, and who know perchance how to use them, are generally too busy to make applications as they should be made. A call of ten minutes must be extended to half or three-quarters of an hour, and his patient will not pay him in proportion to the time expended. The consequence is that nine out of ten of the medical batteries of the general practitioners throughout the country are at the present moment rusting in the closet, the fluid evaporated, and the zincs eaten up.

But there is a wide-spread belief among the *commune vulgus* that "electricity is life." The buzz, the thrill, and the flashes of the battery sustain this biological conviction, warm the imagination, and excite confidence and hope, even if they do not really cause a cure. The doctor must often have a battery to satisfy his patient; and he can actually help him by its psychical effects.

There is probably a steady increase in the use of electricity among American physicians. Instrument-makers inform us that they sell more batteries every year. An intelligent knowledge of what electricity will do has not, however, kept pace with the highly profitable industry of making and mending batteries.

Consequently electro-therapeutics in the hands of many touches on the borders of charlatanry. The claims made for it, even by reputable physicians, are often preposterous. Absurd theories as to its action are advanced, and its practical applications are made without discrimination or skill.

Those who have written most carefully and conscientiously upon electro-therapeutics have shown that its usefulness is more limited than was first believed, but that within its limits it has a remedial power which is unequalled. Scientific investigation has also shown that electricity in diagnosis gives us a precision and help attainable in no other way; and electro-diagnosis is a field which charlatanry does not care to touch.

In practical medicine electricity is of most value as a counter-irritant, a mechanical stimulant and a general tonic. In rheumatic pains and certain forms of neuralgia and in functional asthenic states it does its best work. In paralysis it is a mere symptomatic remedy, much overrated, and generally disappointing. Its power to modify in the slightest degree organic cerebro-spinal diseases is a thing still *sub judice*.

The teachers of medicine in our medical colleges are generally men who are too busy to use electricity, and consequently they know little about it, even its diagnostic value. It would be a wise thing for the colleges to give more of practical instruction regarding the subject, if only to warn students against in future "listening with credulity to the whispers of fancy or pursuing too eagerly the phantoms of hope."

Successful and honest electro-therapy means an expenditure of money, time, and skill.

Dishonest, though perhaps successful, electro-therapy means the indiscriminate buzzing of a vibrator in the ears of every credulous and hypochondriacal visitor.

THE VALUE OF LOCAL MEDICAL JOURNALS.

A Southern contemporary complains that Southern men subscribe for Northern journals, but that Northern men do not subscribe for Southern journals. Granting that this is true, we would say to our Southern brother that men will go where they can get the most and the best for their money, and that no complaints or grumbling can alter the law of supply and demand. Medicine is a cosmopolitan science—it knows no South or East or West. The human race is one, and the laws governing its diseases are the same everywhere. An inflammation, a cancer, a colic, affect alike Hindoo, Hottentot, and, in all respect, our Southern medical editor. The true physician, therefore, will encourage whatever tends best to help along his science and art, and will not hamper progress for the sake of gratifying local pride.

At the same time, we fully believe in the great value of local medical journals, and would urge their generous support (if they are worthy) by the profession. For it is true that somewhat different diseases prevail in one country from those in another, and that race, climate, and other factors may modify slightly the physiognomy of the same disease. Local journals may be of service in interpreting these differences. But, more than that, the local medical journal has an important function in uniting the physicians of a State, in making them known to each other, and in organizing and helping forward movements for the improvement of the profession.

If our contemporary would ask for support upon

grounds such as these, instead of appealing to sectional prejudice and complaining of others' success, it would doubtless receive, and would certainly deserve, a hearty response.

THE NEW YORK ACADEMY OF MEDICINE.

It must now be apparent to all that hostility to this most important institution has been nearly as strong a moving force in causing the recent attempt of a half-dozen malcontents as the bitter hatred of its President. Very many who were dragooned, by specious pretence and plausible fallacies, to attend the meeting of the Academy in April, 1883, and vote for a measure which would have stopped its work and its usefulness, from the conviction that they were thus doing their best to maintain the National Code, have expressed not only their regret but their deep disgust, when they have come to see that they were not working for principle but for the gratification of personal malice. The few words from the President, on resuming the chair, tell the whole story, and were so devoid of personal feeling, and in such excellent taste, that we deem them worthy of being again repeated in this connection: "The Academy will now resume its scientific work, which it has so zealously, efficiently, and harmoniously carried on for thirteen months, until now interrupted by this supreme effort to elevate the character of the medical profession."

THE MEDICAL PROFESSION OF THIS CITY.

The question is often asked by those from other parts of the country, "How is it that such fights are going on in your city, which shock us who do not comprehend them? There is the same diversity of opinion in regard to the necessity and utility of the National Code as with you, but it has never assumed such proportions as with you. It does not break personal friendship, nor do any of us think that sound ethics, the honor of the profession, or its standing in the community, can be best promoted by personal abuse, detraction, or calumny." Some good always comes out of evil. The reproach will now be wiped out. The audacity of four or five, in assuming to be leaders of the City and State in all active movements, speciously but avowedly for the support of the National Code, has now shown them to be the most notorious and conspicuous violators of its spirit. The President of the Academy has, and always has had, as warm friends in this city among the avowed advocates of the Old as of the New Code. In other cities and other parts of the country it is probable that a majority of the prominent men in the profession, who are his friends, are pronounced advocates of the Old Code. The mask of honest purpose has now been torn away from such dangerous leaders, and the true visage of implacable, unrelenting, and unprincipled malignity has been revealed in all its hideousness. We feel assured that among the two thousand (?) physicians of this city and Brooklyn not fifty can be found who are not in hearty accord with this view.

It is, perhaps, worthy of mention that not one of the leaders in the recent events, which have so stirred the profession of this city, is known as an active, much less as a prominent, practitioner of medicine.

BELLEVUE HOSPITAL MEDICAL COLLEGE.

The announcement of the Faculty of this College for two years past has conspicuously inserted this sentence:

"The standard of Medical Ethics recognized by the College is embodied in the Code of Ethics of the American Medical Association."

No other colleges, so far as we have noticed, have felt it necessary thus to advertise their goodness. It was a novel bid for students. As a matter of taste, it seems as absurd as it would be for a lady of good social position and unblemished character to inform all that she met that she was virtuous.

It was undoubtedly believed to be a politic move; whether it has proved so or not can only be determined by comparing the number of students of two years past with the number the two years before, and also comparing these numbers with those in the two other colleges of this city during the same period.

But the question is now asked, whether this standard is intended to apply only to students, or is to have equal force in regulating the Faculty. Tacit acquiescence in the conduct of one of their number, who, by his extraordinary and unparalleled efforts as a volunteer police detective in a foreign country, obtained a kind of negative evidence which would never have been admitted in any court of law in proof of a charge, but would, if not refuted, have a kind of moral force to tarnish the reputation of another member, who is at least the peer of any member of the Faculty, will answer the question. If the Faculty are in doubt in regard to the matter, they may perhaps study with profit a very able commentary on Ethics by another of their number, which first appeared in the New York *Medical Journal*, and was afterward published in a separate volume.

THE FIRST TOTAL REMOVAL OF THE CEREBELLUM IN A DOG.

Professor Luciani has succeeded, by infinite care and the strictest application of modern surgical principles, in totally removing the cerebellum of a dog without destroying life. This single success seems likely to sweep away a world of carefully built hypotheses regarding the function of the cerebellum. During the stage of healing and irritation inco-ordination symptoms appear, similar to those usually observed in birds. As recovery advances, however, these disappear, and a kind of muscular asthenia or loss of tone takes its place.

The experiment confirms apparently the views of Herbert Spencer, Jackson, and Ross, as to the "tonic" innervation of the muscles by the cerebellum.

The description of the effects of the operation is well given in the *British Medical Journal*, which says:

"When healing is finished, the so-called inco-ordination (contractures and pseudo-paralytic debility) disappears, the animal can walk for longer and longer distances without falling. What strikes the observer is the deficient proportion, firmness, and tone of the individual muscular contractions, and their want of fusion; in a word, a kind of 'cerebellar ataxy,' difficult to describe accurately. This disorder of the movements is not, as the 'inco-ordination' of the first period, sufficiently serious to prevent the animal from effecting its various voluntary acts; and,

upon closer investigation, resolves itself into a kind (not of paralysis nor paresis, but) of motor 'asthenia.' For instance, if, instead of walking, the dog were made to swim in a pond, then its movements were perfectly normal. Not the least sign of want of equilibration was noticeable; the four limbs acted with ease, the animal being propelled in the water just as it had been noticed to do before the operation, showing a full co-ordination and adaptation of the individual movements necessary to the performance of the action. But, on arriving at the edge of the pond, the dog was unable to get a footing, in spite of its efforts. Professor Luciani lays stress upon the great difference between the normal behavior of the dog while swimming, and its disturbed motility when performing acts requiring a greater development of muscular energy; and concludes that the 'cerebellar ataxy' just described, is merely a manifestation of a kind of motor asthenia, that is to say, of the insufficient muscular tone, or influence exercised by the nerve-centres upon the voluntary muscles."

THE ALLEGED "VACCINE" AGAINST YELLOW FEVER.

The *Daily Times* gives as news some account of the discoveries of Dr. Domingos Freire regarding the discovery of a yellow fever germ and yellow fever vaccine; and our contemporary wonders why the discovery does not attract more attention. Some of our medical contemporaries have also been heralding the discovery as something very new. The fact is, however, that Dr. Freire wrote a very full account of his work to the *Sanitary News* several months ago, and long before M. Bouley presented the subject to the Académie de Médicine. At an earlier time we gave an abstract of his conclusions, and added the opinion, which we still hold, that Dr. Freire has yet to win a reputation as a trustworthy observer. Some of his previous "discoveries" in bacteriology have turned out to be no discoveries at all.

THE A. C. E. MIXTURE, NITROUS OXIDE, AND ETHER.

In one of the periodical discussions upon anæsthetics which recently took place before the London Medical Society, some more than ordinarily useful facts and conclusions were drawn out. These may be formulated as follows:

First.—British surgeons are giving up the routine use of chloroform, except perhaps with children.

Second.—The A. C. E. mixture was shown to be safer than chloroform, and almost as safe as ether, while more convenient. This mixture is composed of one part, by measure, of alcohol to two parts (measured) of chloroform and three of ether. This mixture should be made afresh just before being required for use. A drawback to its employment, though a small one, is that, in practice, it is found to act a little less rapidly than chloroform in the production of insensibility. It requires no complicated apparatus for its use, being doled out drop by drop on a napkin; and, as an accumulating experience of many years in several metropolitan hospitals appears to testify, it is superior in point of safety for adult patients to chloroform alone. The exhilarating effects of the three parts of ether appear, in practice, to counterbalance the properties of the two parts of chloroform as a cardiac depressor.

One surgeon, Mr. Estes, uses chloroform for young children and the A. C. E. mixture for persons between the ages of six and eight and sixteen and eighteen.

Third.—For safety no anæsthetics equal ether and nitrous oxide.

Fourth.—For both safety and rapidity, no other anæsthetics equal nitrous oxide gas and ether given together. The only objection to this combination appears to be connected with the apparatus that has to be employed. It is bulky, and demands a larger initial outlay than practitioners throughout the country, who seldom require to administer anæsthetics, would be disposed to incur. Still, for all who can employ them, nitrous oxide used with ether possess advantages not found in any other single anæsthetic agent, or combination of agents, at the present day known.

News of the Week.

Medico-Legal Science in New York City.—At the last meeting of the New York Medico-Legal Society, Professor R. Ogden Doremus was elected President. At the last meeting of the Society of Medical Jurisprudence, Dr. Frank H. Hamilton was elected President. Both of these Societies have been working hard during the past year, and have succeeded in attracting a good deal of attention to medico-legal subjects. The Society of Medical Jurisprudence is the result of a protest against, and a "bolt" from, the Medical-Legal Society and its management; and is hampered only by its youth. The Medico-Legal Society has been seriously, if not irretrievably, injured by the fatuous ambition of a lawyer who seems to have no other aim in life than to be its president and manager. It is much to be hoped that under Professor Doremus the Society may regain some of its lost prestige.

Aseptol, a New Antiseptic, says M. E. Transer, has for its scientific name orthoxyphenyl—sulphurous acid. It is an acid phenol, capable of neutralizing ammoniacal bases. It is said to be preferable to phenol as an antiseptic, because it possesses the decided advantage of not being poisonous.

In the Death of Dr. Edward Jarvis, which occurred recently, in the eighty-first year of his age, the medical profession has lost one of its most useful and distinguished members. From an interesting account of his life in the Boston *Medical and Surgical Journal*, we learn that Dr. Jarvis was one of the members of the Corporation of the Perkins Institution for the Education of the Blind; he was Superintendent of the School for Feeble-Minded Youths; Trustee of the Worcester Lunatic Hospital; Consulting Physician to the New England Hospital for Women and Children, and for nearly a third of a century President of the American Statistical Association. Dr. Jarvis was the earliest petitioner to the Legislature for a State Board of Health. He labored year after year, early and late, for its establishment, and he did his best to support it by zealous work. His enumeration of the insane in Massachusetts (Report of 1854),

his essays on political economy, social science, and statistics, and his valuable contributions to the United States Army Reports, gave him well-deserved reputation as a statistician in this country and in Europe. As a kind-hearted citizen and philanthropist, Dr. Jarvis was ever ready with sympathy and help for every person and good cause that needed them, and his public spirit was shown to the last in the gift of his valuable collection of books and reports to Harvard College, the American Statistical Association, and the public libraries of Concord and Boston. He also gave $500 each to Harvard College and the Statistical Association.

The Ohio State Sanitary Association holds its second annual meeting at Columbus, O., February 5 and 6, 1885. The Secretary is Dr. R. Harvey Reed, of Mansfield.

Antipyrin is said to be the most popular of the new antipyretics, and has been the one most imported.

The First Enucleation of the Eye Under Cocaine.—Dr. S. A. Hazen, of Youngstown, O., writes that Dr. Davis, of the same place, enucleated an eye under cocaine about the first week in December, and was the first to perform that operation with the help of the new anæsthetic.

Cultivation of Leprosy Bacilli, and Vaccination for Leprosy.—We learn from California exchanges that Hawaiian physicians have been studying the parasitic origin of leprosy. Experiments are being carried out with the bacillus, and an effort has been made to cultivate it, so that vaccination for leprosy may be practised. An experiment is now being tried in the case of a condemned criminal, who has been inoculated, and whose case will be carefully studied, in the hope that something definite may be learned concerning the dread disease. So much attention has been given to the subject in Honolulu, and the disease is spreading so fast, that the white population has become aroused to the necessity for doing something to protect themselves.

Death of Dr. Charles Clay, one of the Revivers of Ovariotomy.—We learn that Dr. Charles Clay, of Manchester, England, has recently been stricken down by paralysis at the age of eighty-three, and is not expected to live. Mr. Lawson Tait writes of him: "So far as has yet been discovered, the first ovarian tumor removed in England was by the hands of Dr. Charles Clay, on September 27, 1842; all others, with the exception of one by Houston, and another by Lizars, in Scotland, were clearly parovarian cysts. In 1843 Mr. Aston Key removed both ovaries, and Mr. Bransby Cooper also tried the operation in that year, but it was not till 1844 that there was a successful case in London, operated on by Dr. Frederick Bird, followed by one in the practice of Mr. Lane. In the provinces, however, many successful cases had been done. In June, 1848, Dr. Charles Clay published a series of 32 cases with 10 deaths, and in 1857 he had completed 77 cases with 24 deaths, and he continued to operate for many years, until he had performed 395 operations, with 101 deaths, his total mortality being fractionally above twenty-five per cent. The only revival of ovariotomy which Sir Spencer Wells can lay any claim to, is after its temporary decadence for two and a half years in London in the hands of Mr. Baker Brown; and even upon this point the evidence is by no means satisfactory. But if it is to be contended that, from the time of McDowell till 1857, there was nothing done in ovariotomy, and that the revival took place in that year at the hands of Mr. Spencer Wells, I say it may as well be claimed for him that he revived the moon. To Dr. Charles Clay is due the credit of having established ovariotomy in England, and carried it through its early struggles. His practice was a mistaken one in the use of the long ligatures, but its results were certainly no worse than those obtained by the clamp. Dr. Clay, unfortunately, did not know of the results obtained by Nathan Smith from the use of the short ligature. Had he done so, abdominal surgery would have been half a century in advance of its present position, for then it would have been impossible for the clamp ever to have made its appearance. Baker Brown re-introduced Nathan Smith's principle, and Keith has brought it to perfection."

The Therapeutic Effect of Prayer.—Dr. L. A. Wohlfarth, in the *Medical Index*, reports a very excellent result from prayer. His patient was a woman who, two weeks before, had been delivered of a child. She suffered from great mental excitement and a delusion that she must die. He says: "Acting on a hypothesis of psychological therapeutics, and thinking that a 'prayer' offered by an old, respected, and much desired friend like Mr. Davis, possibly might have a salutary influence on a diseased mind to dispel the 'notion of dying,' accompanied by Mr. Moses, I called on Mr. Davis and requested him to see Mrs. Thomas, and 'if occasion should offer,' to give prayer, but to formulate the language of his prayer in a hopeful and inspiring tone. The old gentleman consented, and at my next visit I found the result of his 'prayer' almost miraculous. The 'notion of dying' had nearly left my patient; she was doing well. The puerperal mania was cured, but the patient subsequently died from hypostatic pneumonia."

Fewer Medical Students.—Reports seem to show that in most of the larger medical colleges the number of students this year is somewhat below the average. If this is a fact, it is to be attributed to the hard times, and to the very universal opinion among non-teaching doctors that there have been too many students in the past.

Suicide of a Physician accused of Malpractice.—Vienna medical circles are excited over the suicide of a Dr. Spitzer, who was charged with maltreatment of a case, his applications to an injured limb having apparently been the cause of acute gangrene. During the course of his trial, Dr. Spitzer disappeared, and his body was subsequently found in the Danube.

Renal Calculus Caught in the Urethra, Retention of Urine, Convulsions, Urethrotomy, Cure.—Dr. E. D. Coonley, of Mariner's Harbor, Staten Island, was called to see a boy, aged twelve, suffering from severe pain in the side. An opiate was given and relief followed. Three days later the doctor was called again and found the boy in convulsions and apparently dying. He had not passed water for two days. An obstruction was found in the urethra near the junction of the scrotum and perineum. External urethrotomy was performed, and an ovoid uric acid calculus, weighing 13 grains, was extracted. The boy recovered.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 18, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT appointed Drs. H. D. Nicoll and S. F. Morris, who, with the Assistant Secretary, shall constitute a Board of Inspectors at the next annual meeting, to be held January 15, 1885, the first Thursday in the month falling on the first day of January.

The President then called Dr. R. F. Weir, First Vice-President, to the Chair.

DR. WEIR announced as the next order of business

REPORT OF THE COMMITTEE ON ETHICS, ON CHARGES PREFERRED AGAINST A FELLOW.

DR. ELLSWORTH ELIOT remarked that it had been customary, and moved that the hearing of the report be postponed until after the scientific business of the evening. Lost.

DR. W. T. WHITE said it had been customary, and moved that the Academy go into executive session, which would exclude the representatives of the daily press that had no right to the proceedings, and also remove medical students and others who had no right to participate.

DR. E. D. HUDSON, Jr., opposed the motion on the ground that one side of the question, namely, that presented by the accusers, had already in some mysterious way, perhaps not so mysterious after all, found publication in some of the daily papers, and now *all the proceedings* should be open and above board. The Academy should not countenance any "star-chamber" inquiry.

DR. F. V. WHITE favored an executive session because it was improper for the Academy to wash its "dirty linen" in public, and besides it was contrary to the spirit of the by-laws and constitution of the organization.

The motion was put and lost.

DR. ANDREW H. SMITH, Chairman of the Committee on Ethics, then read the *unanimous* report of the Committee, reached as the result of repeated sittings conducted with all possible precautions at every step of the entire investigation. It was that the charges against a Fellow, of having claimed a degree of M.D., which he never possessed, and of having falsely signed his name upon the signature book of the New York Academy of Medicine, also upon the register of physicians at the office of the Clerk of the County of New York, in 1880, and at divers times and places, were unsustained, the Committee finding them to be without foundation and absolutely untrue.

The report was signed by the Chairman and the other members of the Committee, Drs. V. P. Gibney, C. A. Leale, H. E. Crampton, and C. D. Varley, Secretary.

The report was received with immense applause, and was accepted and adopted without a dissenting voice.

DR. C. R. AGNEW moved that the report of the Committee of Ethics be spread *in full* upon the minutes of the Academy. Carried.

DR. J. W. HOWE remarked that it appeared from the report of the Committee that the signature of the accused in the book of signatures of the Academy had been tampered with, probably falsified, and he therefore moved that a Committee of Three be appointed by the Chair to investigate with reference to the source of the mutilation of the records, and to report to the Academy. Carried.

The VICE-PRESIDENT announced that he would appoint the Committee subsequently.

DR. JOHN C. PETERS directed attention to the point that it was the duty of the accusers to have complied with the by-laws, first notified the accused that the charges were to be made, and then called for a *court medicale*, in which efforts could be made to adjust the differences by arbitration; that only when efforts had failed in this direction to accomplish the desired end, were the accusers justified in bringing the subject before the Academy. He therefore moved a vote of censure for the accusers because they did not observe the rules of professional courtesy laid down by the State Medical Society and the by-laws of the Academy.

DR. ROOSA moved to amend by asking the Fellows who signed the charges to send in their resignations.

DR. PETERS accepted the amendment.

DR. JACOBI was willing to vote to censure the Fellows who signed the charges, but was not ready to vote for Dr. Roosa's amendment, which, if carried, would be practically an expulsion.

DR. WYLIE thought it perhaps not exactly fair to ask *all* the Fellows who signed the charges to resign.

DR. POOLEY moved as an amendment that the Fellows who signed the charges be expelled.

DR. HENRY supported Dr. Pooley's amendment with a vigorous speech, in which he claimed that not a scintilla of testimony had been adduced by the accusers which would be admitted as evidence in a court of law, and that every one, from the giant of the outrage to the babies who signed with him, deserved expulsion. There was not a club or association of gentlemen anywhere in the world that would not expel any member for the same offence, and without another word being said in their condemnation other than that which had appeared in the most admirable report of the Committee.

DR. J. C. DALTON thought that after hearing the complete, thorough, and exhaustive report of the Committee on Ethics, the Fellows should be satisfied that the question had been set at rest. The report was exactly what the Academy wanted, and he felt that the Fellows should be content to adopt the report, because they could not have anything that was better, and it was very easy to have something worse. He therefore moved to lay upon the table all the motions and amendments offered after the unanimous adoption of the report.

THE PRESIDENT was allowed to say that he most heartily approved of the sentiments expressed by Dr. Dalton; that he felt satisfied with the action which the Academy had taken, and that he thought it would be injurious to resort to any extreme measures.

The motion and the amendments were then withdrawn, and the Academy proceeded with the regular order of business.

THE PRESIDENT, on resuming the chair, said: "Here endeth the second lesson. The Academy will now resume its scientific work, which has been continued harmoniously for thirteen months, until interrupted by this supreme effort to elevate the character of the medical profession."

At the request of the author, the reading of Dr. Gaspar Griswold's paper on "Electricity as a Cardiac and Respiratory Stimulant," was postponed until some future meeting.

DR. A. M. JACOBUS introduced the following resolutions, with a preamble, which were adopted.

MEDICAL EDUCATION AND A STATE BOARD OF EXAMINERS.

Resolved, That the Committee on Medical Education of this Academy be instructed to inquire into the question, whether it be advisable to have a "State Board of Examiners," and also as to the import of any proposed bills and such other matters pertaining to the general subject as to them shall appear pertinent.

Resolved, That the Committee be directed to report at the stated meeting of the Academy, to be held January 15, 1885, and that such report be made one of the special orders for that meeting.

The Secretary, DR. KATZENBACH, read a letter received from Dr. S. T. Hubbard, in which he withdrew his name from the list of nominations for President.

The resignation of Dr. Horatio Gomez was accepted, and the time for Dr. Woolsey Johnson to sign the by-laws extended, after which the Academy adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 22, 1884.

DANIEL LEWIS, M.D., PRESIDENT, IN THE CHAIR.

THE PHYSIOLOGICAL AND THERAPEUTIC EFFECTS OF THE COCA LEAF AND ITS ALKALOID.

DR. WILLIAM OLIVER MOORE read a paper on the above subject in which he reviewed the literature of the drug, and gave an account of the various uses which have been made of it. Especial attention was directed to its general tonic effects, its use in the treatment of affections of the larynx, pharynx, and tonsils, and in the treatment of the opium habit, where it had been reported to be of service.

Attention was then directed to the use of the alkaloid cocaine, its first effect being to produce anæmia, and second, anæsthesia of the parts to which it is applied, the effect being especially marked on mucous membranes. Instillations into the eye of the affected side had proved very serviceable in cases of hemicrania, and Dr. Moore suggested that the alkaloid might afford relief in seasickness. In operations involving the skin the effect of the alkaloid was very much enhanced by first removing the epidermis.

The discussion was opened by DR. ROOSA, who thought that the enthusiasm of the ophthalmologists might be excused, even in the glare of the luminous remark in THE MEDICAL RECORD concerning "the lonesome man," since it had been established beyond doubt that in a very large number of operations heretofore requiring the use of general anæsthetics, the smothering cone, and not only that but, what was more important, the pain, had been done away with, a triumph which no one was better qualified to appreciate than the editor of THE MEDICAL RECORD himself.

The only disappointment which Dr. Roosa had to record was concerning the value of cocaine in otology, where he was not as yet at all satisfied as to its true place as a therapeutic agent. It should be remembered, however, that to determine the true therapeutical effect of drugs was a much more difficult problem to solve, than to merely learn what the effects were which these drugs produced when applied locally.

DR. WILLIAM M. POLK, with reference to gynecological practice, had found that the best method of using cocaine was by hypodermic injection. For example, in several cases of laceration of the cervix, he had been able to operate without pain to the patient, by injecting four minims of a four per cent. water solution into the tissue of the cervix on each side shortly before beginning with the knife. In certain patients belonging to this class, therefore, he believed it had a limited application.

In the removal of the wire sutures after ordinary perineorrhaphy, he had found it especially serviceable. He had also used it successfully before applying the actual cautery to carcinoma of the cervix extending to the vagina, and also before using caustics in the treatment of chancre and chancroid.

With the assistance of Dr. Le Fevre, of Bellevue Hospital, the hypodermic use of cocaine behind and in front of the cervix uteri, had mollified the severity of labor pains very markedly.

A curious fact also obtained in those cases, namely, there was anæsthesia of the cornea.

In one case he had performed hepatotomy, for hydatid cyst and abscess, with the aid of cocaine applied locally. The local anæsthetic was used, because of the bad general condition of the patient, which contra-indicated the use of either ether or chloroform.

DR. KNAPP had noticed that dilatation of the pupil, *ad maximum*, was not produced by cocaine.

DR. POOLEY thought the use must be abandoned in a certain number of cases occurring in children, because of the fright and agitation which occurred without the use of a general anæsthetic. He also regarded the method of injecting the orbital tissues as a procedure liable to be attended with disastrous consequences, hence should be adopted only with the greatest care.

In one case he had noticed marked toxic effect of the drug ten minutes after a single instillation of a four per cent. solution into the eye. There was pronounced vertigo, and the pupil in that case was apparently dilated *ad maximum*. He had relieved the patient in one case of hemicrania, by a single instillation into the eye upon the affected side.

DR. HOPE spoke of the efficacy of cocaine as a local anæsthetic in a case of laryngeal growth.

DR. F. A. CASTLE referred to points in the literature of the subject and also in the modes of obtaining the alkaloid. He also directed attention to the local anæsthetic effects produced by certain other drugs, as cannabis indica, kola-nut, etc., with which experiments were being made.

Practically, he had used cocaine in a case of urethral stricture, which he was able to dilate without producing very much pain, and also in a case of sensitive nipples, with considerable benefit.

DR. W. F. MITTENDORF thought that the peculiar effect of cocaine was produced by its action on the capillaries, first causing anæmia about the terminal nerve-fibres, and that this anæmia was the principal factor in developing the local anæsthesia.

With reference to the mydriatic effect, he believed it to be due to the action of the alkaloid upon the sympathetic nerve-fibres. He did not agree with Dr. Pooley, and thought that the best effects of the drug were obtained in the treatment of children. The pressure of the eye-speculum sometimes complained of, he had been able to overcome by the use of his own instrument.

DR. J. LEONARD CORNING spoke of the effect produced by coca in the central nervous system, and had found it especially serviceable in the treatment of anæmic, hysterical, neurasthenic females, the spinal concussion of Erichsen, etc.

DR. WILLIAM H. THOMSON, from a tolerably large experience in both hospital and private practice, had reached the conclusion that the value of coca as a medicine was about equal to that of boneset; not quite so good as fresh boneset. This, however, did not at all militate against its value as a local anæsthetic.

He had used cocaine as a local application in the treatment of pruritus vulvæ, with exceedingly satisfactory results.

DR. SELL spoke of the use of avena sativa in the treatment of the opium habit.

THE SECRETARY read the following communication from DR. A. P. MEYLERT, which had a bearing upon the question of the therapeutical value of coca, and also of the value of the coca and its alkaloid, in the treatment of the opium habit:

"So much has been written about the value of this drug in cases of opium habituation that I have many times endeavored to use the various preparations of coca leaf in this disorder, but little advantage has resulted therefrom. Alcoholic preparations were contra-indicated in many cases complicated with chronic alcoholism, and in my judgment were hazardous in other cases from the tendency in habit cases to inebriety. The fluid extract of coca in small doses was without apparent effect, and in large doses was nauseating. The solid extract in pill form seemed almost inert.

"It was therefore with gladness that I read of the new anæsthetic—the cocaine alkaloid—and hastened to give it a trial as a substitute for morphia in habit cases.

"I have used it both by the mouth and subcutaneously, using a solution of sixteen grains in the fluid ounce, being one grain in thirty minims.

"I will give the general results briefly so far as observed, reserving details for the future.

"Administered alone in doses of five to ten minims, there was no effect which I could fairly attribute to the

drug. In doses of fifteen to twenty minims, equal to one-half to two-thirds of a grain, there was little if any relief from pain or from the hyperæsthesia and general uneasiness of the patient, but the face became pallid, the pulse small, and a sense of exhaustion followed. From this, however, the patient quickly rallied on administering the usual dose of morphia.

"When the alkaloid was administered subcutaneously *with* a solution of morphia, the only perceptible effect of the cocaine was to enhance somewhat the exhilarating effect of the morphia. It did not, however, prolong the period of quiescence induced by the dose of morphia, nor could a less quantity of the narcotic satisfy the patient.

"On the day subsequent to the administration of the cocaine, however, a larger reduction of the morphia was easily tolerated.

"The above doses are doubtless large, except for those taking five to thirty grains of morphia daily.

"I am therefore pursuing these investigations with great interest, and hope to hear the experience of other observers in this field."

The discussion was closed by Dr. Moore, after which the Society adjourned.

New Instruments.

FLEXED SPLINTS.

Dr. W. D. Kearns, of Pittsburg, Pa., introduces, in a paper read by him before the Allegheny County Medical Society, somewhat of a novelty in the form of "flexed splints." In presenting them to the profession, he has been encouraged and sustained not only by personal tests, but also by the approval of recognized authority, in regard to the soundness and feasibility of the principles evolved, especially referring to Colles' fracture.

Dr. Kearns reviews the several varieties of splints usually employed, condemning some, and calling attention to the incompetency of the straight padded splint to secure the necessary angles of flexion of the wrist-joint and metacarpo-phalangeal articulation; at the same time suggesting the congruity of a flexed splint. He considers the latter less complicated than the padded straight splint, inasmuch as the bend of the wrist and hand is at once permanently fixed. Whether, he advises, the fracture of the radius is transverse, oblique, more or less longitudinal, or more or less comminuted, the conditions governing the form of the retaining splints, after complete reduction, are equally exacting, and are best subserved by flexed splints, through their greater efficiency in forestalling the formidable impairment of the functions of flexion, extension, pronation, and supination.

He also directs attention, comparatively, to fractures of the radius and ulna, and the necessity, after complete reduction, of maintaining relaxation of the several muscular tendons, fasciæ, and ligaments, and that the continued maintenance of this relaxation is also of paramount importance in connection with fractures of the wrist; and it is claimed that flexed splints will admit and secure correlative relaxation. Flexed splints, he finds, propose a ready, comfortable, and efficient maintenance of all appreciable required muscular relaxation of the extensors and flexors to their insertions along the phalanges, and of the muscles and fasciæ of the hand and thumb; and, also, may claim a great advantage in securing the more early, free, and full use of the hand.

The insertion of thin, narrow, interosseous pads are employed, and materially control the displacing influences of the pronator quadratus and the supinator longus. Interosseous pads, he finds, will also fully compensate the pistol-shaped splint of Nélaton, in preventing the approach of the fragments to the ulna. Short splints, or a short palmar splint and a long, straight dorsal splint, he considers inadequate to immobilize the proximal joint. An "immediate" bandage, if loosely and intelligently applied, will advantageously subserve its purpose in preventing muscular contraction.

He observes that the angle of flexion of the dorsal splint (Fig. 1) is made studiously sharp at the wrist, carefully evading pressure on the carpal bones. This angle should also be of degree sufficient (about 122° Fig. 1), by the backward bend of the hand, to secure complete relaxation of the posterior muscular tendons; while the anterior relaxation is effected by the partial closing of the hand. The splints admit a slight drooping of the hand (the natural curve of uncontrolled muscular action).

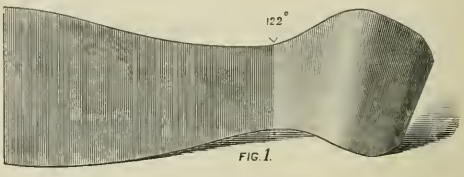

FIG. 1.

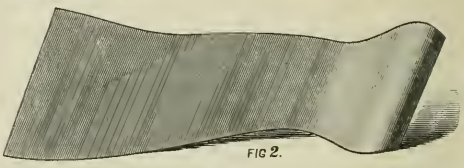

FIG. 2.

The accompanying woodcut traces the anterior edge of the palmar splint (Fig. 2) as a continuous line fully over the muscular prominence of the three flexors of the palmar surface of the thumb, preserving their full unconstraint, whence it inclines underneath the thumb along the index finger, restoring the width of the splint to that of the hand. Wooden splints, which can now be readily sawn, he considers practically the best. They can, however, be constructed of sheet zinc, which, judging from the specimens sent us, would also serve an excellent purpose.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 7 to December 20, 1884.

Hammond, John F., Colonel and Surgeon. Retired from active service, by operation of law, on December 7, 1884, under provision of Act of Congress approved June 30, 1882. S. O. 287, A. G. O., December 8, 1884.

McKee, J. C., Major and Surgeon. Leave of absence still further extended one month. S. O. 288, A. G. O., December 9, 1884.

Porter, Joseph Y., Captain and Assistant Surgeon. Sick leave of absence extended four months, on surgeon's certificate of disability. S. O. 286, A. G. O., December 6, 1884.

Kane, John J., Captain and Assistant Surgeon. From Department of the East to Willet's Point, New York. S. O. 286, A. G. O., December 6, 1884.

Banister, J. M., Captain and Assistant Surgeon (Fort Adams, R. I.). Granted one month's leave of absence, on surgeon's certificate of disability. S. O. 251, Department of the East, December 9, 1884.

Gray, Charles C., Major (retired). Died at Geneva, N. Y., November 22, 1884, instead of November 26th, as heretofore announced. Circular Orders, A. G. O., December 8, 1884.

Lauderdale, John V., Captain and Assistant Surgeon. Fort Sully, D. T. Granted leave of absence for one month, to take effect about December 20, 1884. S. O. 146, Department of Dakota, December 9, 1884.

COMEGYS, E. T., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 234, Department of the Missouri, December 8, 1884.

PILCHER, J. E., First Lieutenant and Assistant Surgeon. Ordered to Fort Custer, M. T., for duty. Order assigning him to duty at Fort A. Lincoln, D. T., amended. S. O. 145, Department of Dakota, December 8, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending December 13, 1884.

CRAIG, T. C., Passed Assistant Surgeon. Detached from Alliance and placed on waiting orders. December 6, 1884.

CURTIS, L. W., Assistant Surgeon. To the Naval Hospital, Chelsea. December 9, 1884.

GAINES, J. H., Passed Assistant Surgeon. Present duty continued.

GREEN, E. H., Passed Assistant Surgeon. Special duty at Museum of Hygiene, Washington. December 11, 1884.

MEURRAY, J. M., Passed Assistant Surgeon. Detached from Naval Hospital, Chelsea, to the Flagship Hartford. December 9, 1884.

WOOLVERTON, T., Surgeon. To the Shenandoah. December 6, 1884.

Correspondence.

CARD FROM DR. FORDYCE BARKER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you allow me a small space to express the deep feeling which has touched my heart by the reception of a great number of letters since last Friday morning?

As from members of the medical profession of this city and Brooklyn, I have already received more than two hundred, and very many letters and telegrams from other places, it is quite impossible for me to send an acknowledgment to each writer, I must pray my friends to accept my thanks through the medium of your journal.

FORDYCE BARKER.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 20, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
December 13, 1884.....	0	27	70	6	118	68	0	0
December 20, 1884.....	0	25	106	5	130	64	0	0
Deaths.								
December 13, 1884.....	0	9	10	4	13	27	0	0
December 20, 1884.....	0	10	24	6	28	31	0	0

THE PRACTICE OF MEDICINE IN RUSSIA.—A recent number of the *Aerztliches Vereinsblatt* contains an interesting article on "Medicine in Russia," written by a German physician practising in that country. The number of physicians in Russia, according to the official statistics for 1883, is 15,231. Most of these are collected in the cities, while the country is so poorly supplied that there are districts as large as Saxony or Bavaria where there is but one physician. There are medical faculties in Kief, Kazan, Charkov, Moscow, Warsaw, Helsingfors, and Dorpat, the first five of which give instruction in the Russian language, while at Helsingfors Swedish is spoken, and at Dorpat German. There is, besides, an army medical school. In the Russian schools there is a five-years' graded course with yearly examinations. At the end of this course an examination must be passed for the title of physician, after which, if it is so desired, the candidate may pass on to the doctorate examination. In Dorpat there is no graded course, and but two examinations are held. The first, called the *examen phylosophicum*, is passed usually after two or three years' study, and embraces the subjects of chemistry, physics, botany, mineralogy, zoölogy, anatomy, physiology, general pathology, and dietetics. If a student allows four years to elapse after his philosophical examination before coming up for the *rigorosum*, he is obliged to pass the former over again. It sometimes happens that students who become interested in some special subject pass this examination three or four times before coming up for their final. At the final examination, the *examen rigorosum*, the student chooses whether he will try for the title of physician or of doctor. In order to obtain the latter degree a more exact knowledge of theoretical subjects is necessary, and in addition the candidate must write two theses, on given subjects, in Latin. If he is thus far successful he must attend and take part in a dissertation. A doctor ranks as eighth in the classes defined by the State, while a physician is one step farther down the scale. No one can receive an appointment as head physician in a hospital or become a "privat-docent" unless he possess a degree of M.D. Russia has a paternal government, and her medical sons are not neglected, but are placed under the care of the Minister of the Interior. The business of the medical division of the Department of the Interior is defined to be to keep an eye "on the industry and scientific ability of the physicians, and to report thereon yearly." It also takes them under its protection when they are subject to unjust attacks. It has further to see that the sick are treated only by physicians of proved skill, and must warn the people against the dangers of employing charlatans. One article of the medical law provides for the punishment of those who employ quacks. The law also gives the department authority to transfer physicians from one place to another as occasion may require: thus in case of an epidemic in a place where physicians are scarce, the Minister of the Interior can send others from places where they are more plentiful. In the matter of fees the law is also explicit, and as the law was framed in 1789 and has never been altered, it may readily be understood that the lawful fees are not exorbitant. For a visit in the city a doctor's legal charge is 30 copecs (24 cents) if he gives a prescription, and 15 copecs (12 cents) if he writes no prescription. For a visit outside of the city he is allowed to ask 60 copecs (nearly half a dollar). A consultation is held to be worth $1.20. A physician's fee is set down at 12 cents with or without a prescription. For applying a blister or giving an enema he is allowed to ask the enormous sum of 6 cents, and a venesection is held to be of equal value. Wet cups are to be applied at the rate of 2½ cents each. An obstetrician who has assisted at a difficult labor may demand $1.20 for his valuable services. These charges are for attending people in moderate circumstances, and the rich are expected to pay a little more. This is the law as it stands upon the statute book, and which can be enforced at any time, but practically, of course, it is a dead letter, in its good features as well as in its bad ones. There are plenty of quacks who enjoy a lucrative practice, just as is the case in other countries, yet occasionally one of these gentry comes to grief. Not long ago a most elegant gentleman settled in St. Petersburg, professing to be an ardent disciple of Hahnemann, and by reason of his fine presence and engaging manners soon acquired a large practice, some of his patients being

members of a grand ducal family. Before long, however, it was discovered that his sole right to practise consisted in the possession of a diploma from the University of Philadelphia, and he was quickly escorted over the border and earnestly recommended to stay there. The number of homœopathists in Russia is small, yet those who are there are divided into two parties, each calling the other a company of charlatans. Their experience with hospitals was not encouraging. Three years ago they started a hospital for the treatment of diphtheria, which for some time had no inmates. Finally, on the advice of a homœopathic general, a soldier sent his child there for treatment. The child very promptly died, and the hospital received no more cases of diphtheria. Russian medical societies are not very flourishing, owing, the writer says, to an every-man-for-himself spirit that exists among the physicians there. The oldest is the Society of Russian Physicians, founded in 1833. The members of this society are intensely national in their feelings, as was evidenced in one of the addresses at their semi-centennial celebration, when the speaker congratulated his hearers that at last Russian medicine had thrown off the German yoke. This feeling was also exhibited in an order recently promulgated by the Minister of War, to the effect that not more than four per cent. of the army surgeons should be Jews. There are five other societies, one of them composed chiefly of German physicians, in St. Petersburg, and seventy-three in the provinces. In addition there are several mutual aid and benefit societies among medical men. Considerable progress has been made in the last decade in medical journalism. The leading journal is the *Vratch* (the Physician), founded by Manassein in 1880. Next to the *Vratch* comes the *Russkaya Medicina* and the *Meditsinski Vestnik*. Another excellent journal, composed principally of abstracts, but containing also some original aricles, is the *Meditsinskoye Obosrenoye*. The organ of the German physicians is the *St. Petersburger Medicinische Wochenschrift*. The writer says that medical journals are not subject to the censorship of the press, but this seems to be an error, for the last-named journal always bears the imprimatur of the censor. At one time there were many female medical students attending a college of their own, but lately they have been frowned upon by the Government (probably by reason of the Nihilist fright), and now their college is in a fair way of extinction. The students for the most part lived a miserable life, half starved and half frozen, and their condition was not much improved after they had finished their studies. They had no assured standing among physicians, and usually practised in the country districts and among the poorest classes.

The Properties of Crotalus.—Crotalus, the poison of the rattlesnake, is obtained from the *crotalus horridus*. Physiological action: Inoculation causes ecchymoses and hemorrhages, by putting an end to the coagulating power of the blood, with febrile heat, anorexia, injected conjunctiva, etc. Therapeutical uses: It was originally introduced by homœopaths, and has been employed for malignant hemorrhagic scarlatina on the principle "similia similibus curantur." Preparations and doses: The poison-bag is removed from the living vipers, and then mixed with glycerine as a preservative. Crotalus is prepared in decimal strengths, the menstruum used being one part of glycerine to three parts of proof spirit; the three decimal dilution is chiefly used. Dr. Havard, of Liverpool, prescribed three drops in a spoonful of water every three or four hours in malignant hemorrhagic scarlatina. It is also used hypodermically in doses of one to three minims.

The Abuse of Tonics.—Dr. Alfred W. Perry, of San Francisco, Cal., writes: "The abuse of tonics is most notably seen in rather stout persons over forty years old. Such persons, without any serious organic disease, complain of weakness or fatigue after slight exertion, pains in the limbs, vertigo, and perhaps of shortness of breath; and as they are frequently rather pale, tonics and stimulants are prescribed for them. The appetite, and thereby the body-weight, may be increased, but the symptoms complained of remain or are aggravated. Let us take up each symptom and analyze it. Normally fatigue is due, according to late researches of Voit and Pettenkoffer, to an accumulation in the muscle of the products of destructive metamorphosis (lactic acid, creotine acid, phosphate of potassium, sarcosine) produced by exercise, and partly to a decrease of the oxidizable muscular substance. By rest, normally, the blood-current washes out these waste products, and the more nearly the blood approaches a standard healthy condition, the more quickly does this take place. The amount of food consumed by an adult should be just what is required to keep up an average body-weight (in proportion to height), and will vary with the work performed. An excess of food digested and absorbed produces a blood too rich, thick, and imperfectly oxidized. This condition is generally marked by a deposit of reddish urates in the urine when cooling. An addition to the blood in such a condition of large quantities of water (by drinking) enables it to dissolve more easily these waste-products of muscle, and so produces a feeling of renewed strength. Witness the increase of uterine action in labor after drinking freely of any kind of tea; the vigor produced in the plethoric or gouty by drinking freely any kind of mineral water, and using low diet; the undoubted benefit of the present fashion of drinking freely of hot water has the same explanation. The muscular pains are a slight kind of cramp or muscular rheumatism, which is, as Anstie (in his work on neuralgia) defines it, '*pain produced in a muscle obliged to work when its structure is imperfectly nourished or impaired by disease.*' The short breath depends on a relative insufficiency of the heart's action. The heart, without being at all diseased, is often incapable of maintaining the circulation properly with its incidental variations. Let us take the example of a man five feet eight inches in height, one hundred and fifty pounds in weight, and let him increase in weight to two hundred pounds while performing a moderate, and perhaps a decreasing amount of labor. His heart is unable to propel the blood properly through the area of two hundred pounds of body-weight, involving about twenty-five per cent. more work, because the heart-muscle has not increased in bulk and vigor at all. If this man's weight had increased while performing hard work, we might be sure that the cardiac muscle had grown in proportion. Any sustained increase of tension of the circulation causes a physiological hypertrophy of the heart. But where the body-weight increases with a decrease of labor, and an increase of food or alcoholic stimulants, we may be sure that there has been no physiological cardiac hypertrophy. The vertigo often met with in these cases may be the result of a cerebral anæmia. This when conjoined to pallor is usually an indication for tonics and iron. There is no poverty of the blood or general anæmia, the surface is pale from insufficient filling of the capillaries from want of heart vigor. The conditions above cited need a treatment entirely opposed to a tonic one. They need alkalies to assist in breaking down tissue, plenty of water to carry away the broken-down tissues, and a little increase in exercise with a restricted diet."

Harvey as a Student of Nature.—In the Harveian oration for this year Dr. Reynolds lays stress upon the fact that Harvey was always studying and seeking to interpret *nature*. "He was one of her keenest and most devout interpreters; in reverence he knelt before her, and asked her questions; he cross-examined her, but in no unfriendly tone. Nature to him was a perfect verity, the one witness that could never be absorbed or shaken, the one witness in whom there could be no false way, the one witness who could not lie. And by such a method only must science ever be advanced; it is thus that great discoveries are to be achieved, thus that we must seek to leave our footsteps on the sands of Time."

INDEX.

A

Abdominal section, 383.
Abortion, 574; and nitrite of amyl, 621.
Abscess, muscular rupture simulating, 682; of frontal sinus, 163; of the cerebellum, 404; of the liver, 580; orbital, 162; perinephritic, 23.
Academy of Medicine of Paris, 77, 107.
A. C. E. mixture, the, nitrous oxide, and ether, 712.
Acid, borophenylic, 38; carbolic, in rheumatism, 10; hydriodic, in hay asthma, 259; hydrobromic, 222; lactic, 191; osmic, in epilepsy, 317; oxalic, 222; picric, 222; salicylic, in lupus, 541; valerianic, 222.
Accommodation and presbyopia, 586.
Acetabulum, fracture of, 576.
Acne, 628.
Actinomycosis, 26.
Adams, the late Dr. J. G., 18.
Addison's disease, 697.
Adenitis, strumous, treated by nitrate of silver, 375.
Adenolymphangitis, uterine, 333.
Adenoma, of the liver, 706.
Adenopathics, scrofulous, 10.
Adonis vernalis, 192.
Agnew, Dr. C. R., hydrochlorate of cocaine, 438.
Air-passages, foreign body in, 552.
Ankle clonus and patellar reflex, 403.
Albumen, in urine, delicate tests for, 94.
Albuminuria, functional, 305; hepatic, 124; in pregnancy, 331; physiological, 10; regulatory, 601.
Alcohol, 378.
Alcoholism, chronic, 681.
Alimentary canal, nervous origin of some disorders of, 481.
Alt, Dr. Adolph, notice of book by, 299.
Althaus, Dr. Julius, notice of book by, 692.
Alum, 139.
Amaurosis, unilateral, 66.
American Academy of Medicine, 411.
American Gynecological Society, 382; notice of transactions, 1883, 244.
American Laryngological Association viewed from the outside, 308.
American Ophthalmological Society, 161.
American Otological Society, 105.
American Public Health Association, 406, 439.
Amidon, Dr. R. W., notice of manual by, 495.
Ammonia, muriate of, 307.
Ammoniac, gum, 221.
Ammonii, boras, 139; phosphas, 139.
Amyl, nitrite of, and abortion, 621; nitrite of, in ammoniacal urine, 12; nitrite of, in opium-poisoning, 13; nitrite of, internal use of, 308.
Anæmia, essential, 431; following hemorrhage, 301; pernicious, 301; pernicious, in children, 293; iron albuminate in, 140.
Anæsthesia, of the trigeminus with trophic ulceration of the helix, 698; rectal, 72; surgical, 278.
Anæsthetic, whiskey as an, 588.
Anæsthetics, in St. Petersburg, 42.
Andrews, Dr. Joseph A., jequirity ophthalmia, 596.
Aneurism, aortic, 263, 699; inguinal, 166; miliary of the stomach, 97, 293.
Angeiomatous growths, treatment, 28.
Angina pectoris, 550.
Anteflexion of the uterus, 693.
Antipyrin, 56, 245, 393, 713; exanthem following the use of, 317; in diseases of children, 293.
Antipyresis, 493; by inunction, 37.
Antipyretic, 515.
Antisuppurative, 700.
Aphasia, from indigestion, 543; peculiar forms of, 12; sensory, 556.
Apocynum cannabinum, 63.
Apomorphia, 139; and epilepsy, 598.
Arachnoid, lipoma of, 707.
Army surgeons, shall they practise outside? 475.
Arsenic, in generalized sarcoma, 431.
Arteries, coronary, sclerosis of, 682.
Arteritis, obliterous, 99; syphilitic, 599.
Arthropathics, multiple spinal, 67.
Aseptol, a new antiseptic, 600, 712.
Asphyxia, 56.
Asthenopia, 390.
Astringents, in ophthalmic practice, 482, 499.
Ataxia, hereditary, 67; locomotor, 265.
Atropine, at the beginning of convergent squint, 389.
Auricles, cardiac, function of, 575.
Averill, Dr., trichinosis, 140.

B

Baby-farming, 154.
Bacilli, cultivation of, 56; in calcareous concretions of the lungs, 681; tubercle, in the urine and kidneys, 191.
Bacillus of syphilis, 687; tuberculosis, 274.
Baird, Dr. W. T., electricity in pleuritic effusion, 476.
Baker, Rev. Geo. S., correspondence, 446.
Baker, Dr. Henry B., age of greatest risk from consumption, 235.
Baldness, 84.
Baldwin, Dr. B. I., immunity of the negro from trachoma, 704.
Baldwin, Dr. D. A., dysentery, 433.
Barker, Dr. Fordyce, 709, 717.
Barnes' dilator, modification of, 529.
Baruch, Dr. Simon, 224; tracheotomy in croup and diphtheria, 534, 700.
Baths, carbonic-water, 13; cold, in the treatment of puerperal fever, 333; for the poor in winter, 409; for use during the year, 418.
Beard, Dr. Geo. M., book notice [posthumous MS.], 300.
Bell's law discovered by Magendie, 600.
Bellevue Hospital Medical College, 711.
Bemiss, Dr. Samuel M., notice of death of, 571.
Benzoin, 168.
Bergh and Pasteur, 18.
Berlin Society of International Medicine, 52, 191, 245.
Billings, Dr. Frank S., book notice, 216.
Billings, Dr. John S., book notice, 524.
Binnie, Dr. John, artificial feeding of infants, 287.
Binz, von, Prof. C., notice of book by, 19.
Biological Society of Paris, 78, 108, 193, 246.
Black, Dr. G. V., notice of book by, 691.
Blackwell, Dr. Elizabeth, book notice, 495.
Bladder, aspiration of, 236; cider as a prophylactic in stone of the, 10; extraction of foreign bodies from, 184; exstroversion of, 302; foreign bodies in, 432; injections of, 269; local use of ether in the, 25. nitrate of silver injections of the, 501.
Blindness, fulminating, 161; in infancy, 10.
Blood, condition of, in hydrophobia, 266; transfusion of peptonized, 108; transfusion of, is it justifiable? 708.
Blood-poisoning from human bites, 682.
Blood-vessels, physio-pathology of the, 69.
Bodenhamer, Dr William, the rectum a receptacle for excremental matter, 309.
Body, human, motor power of, 476.
Bones, brittle, 10.
Borax, in contagious diseases, 266.
Borcheim, Dr L. E., tape-worm, 429.
Bosworth, Dr. F. H., a new therapeutic use for cocaine, 533; the three tonsils, 365.
Bow-legs, 612.
Boyland, Dr. G. Halsted, Florida climate, 109.
Brachydactylus, symmetrical, 377.
Bradner, Dr. Wm. B., climate of Florida, 83.
Brain, abscess cavities in the, 235; bony tumor of, 707; cortical lesions of the, 237; fourth ventricle, 249; pressure, in public schools, 492.
Breast, tubercles of the, 39; tumor of, 554.
Breathing, buccal, 565.
Breech, cases, 579.
Bright's disease, dyspnœa of, 681; of malarial origin, 237.
British Medical Association, 126, 131, 160, 217.
Bronchitis, 542.
Brown, Dr. R. Wood, dead teeth in jaws, 564.
Browning, Dr. William, pseudo-bulbar paralysis, 487.
Buboes, suppurating, 376.
Buck, Dr. Albert H., deafness of supposed syphilitic origin, 257.
Bundy, Dr. A. D., death from the introduction of a stomach-tube, 504.
Burke, Dr. John, 251.
Burnett, Dr. Charles H., notice of book by, 691.
Burns, 97.
Burq, Dr., death notice, 241.

C

Cæsarean section, 329.
Caffeine, 191, 491.
Calculi, renal, removal by manipulation, 587.
Calculus, biliary, passed by the rectum, 599; impacted in the ureter, 541.
Calomel, in diphtheria and croup, 36; in diseases of the eye, 38; in the treatment of pneumonia, 683.
Campbell, Dr. S. E., 306.
Cancer, early recognition of, 135; from cicatrices in the stomach, 270; of the breast, 670; of the pancreas, 532; of the stomach, 385, 469; of the stomach and pancreas, 593; statistics in England, 223; vaginal hysterectomy for, 384.
Canfield, Dr. H. A., 448.
Cannibalism, is it necessarily murder? 531.
Capsule, internal (brain), 477.
Carcinosis, general, 552.
Cardiopathy, of menopause, 347.
Carman, Dr. J. H., opium-smoking, 501.
Carotid, ligation of common, 456.
Carhart, Dr. J. W., correspondence, 475.
Case, Dr. Meigs, special disease of spinal curvatures, 701.
Cataract, artificial maturation of, 388; natural history of, 102.
Catarrh, chronic intestinal, 573; intestinal, 432.
Catheter, passage of, 456.
Cauldwell, Dr. C. M., manaca in rheumatism, 31.
Caustics, in ophthalmic practice, 482, 499.
Cauterizations, punctate, 51.
Cephalhydrocele, traumatic, 236.
Cerebellum, abscess of, 404; the first total removal of, in a dog, 711; morphological status of the, 111, 249.
Cerebral localization, 146, 232, 342, 458, 536.
Cerebrum, anæmiants and hyperæmiants, 112.
Cesspools, 101.
Chamberlain, Dr. C. W., death notice, 241.
Chamberlain, Dr. William M., correspondence, 664.
Chancre, excision of, 360.
Chapman, Dr. Henry C., book notice, 216.
Chapin, Dr. Henry Dwight, the prevention of summer complaint, 87.
Charles, Dr. T. Cranstown, notice of book by, 692.
Cheesman, Dr. W. S., supernumerary testicles, 196.

Chesney, Dr. J. Portman, book notice, 244.
Children, convulsions in, 543.
Childs, Dr. S. B., dysentery, 223.
Chill, in pneumonia, 13.
Chloroform, dosimetric administration of, 39; for tape-worm, 112, 308, 475, 601; narcosis maintained for eight days, 108.
Chloral, oleate of, for pruritus, 543.
Chloral-quinine, 196.
Chlorosis, 301.
Cholecystotomy, 516.
Cholera, Asiatic, 73, 100, 130, 156, 245, 260, 440, 522, 548, 550, 589, 661; and cholera nostras, 604; and the comma-bacillus, 53, 241, 267; and its prevention, 40; and rags, 571; and syphilis, 385; and the Cabinet, 98; and tubercle bacillus, 31; at Suspension Bridge, 1854, 556; bacillus, Koch's defence of, 602; cause of, 11; copper as a prophylactic, 512; French commission, 467; further contributions to, 687; germ, 211, 350; infantum, 357; influence on, by syphilis and mercury, 447; in Europe, 16; in India, 255; in Toulon, 107; intravenous injections in, 688; limitations of knowledge regarding, 570; microbe of, 295; prevention of, 167; quarantine in, 570; sulphuric acid in, 386; the germ and its destruction, 251.
Chordee, 600.
Christian, Dr. E. P., placenta prævia, 89.
Cider, as a prophylactic in stone of the bladder, 10.
Cinchonidia, 532; sulphate of, 72.
Circulation, discovery of the, 224.
Cirrhosis of the liver, 697; of the pancreas, 505.
Civil service and the medical profession, 407.
Clavicle, fracture of, 527.
Clay, Dr. Charles, one of the revivers of ovariotomy, 713.
Clitrophobia, 403.
Club-foot, 277.
Coca, 491.
Coca-leaf and its alkaloid, 510.
Cocaine, muriate of, 153, 417, 438, 534, 550, 577, 604, 656, 715; a new therapeutic use for, 533; early employment of, 659; failures, 658; first enucleation of the eye under, 713; history of properties of, 518; in dentistry, 657; in general surgery, 657; Knapp's experiments, 461, 463; in gynecology, 489, 658; in intranasal surgery, 654; in minor surgery, 582.
Cold, in therapeutics, 397, 414.
Colic, clinical forms of hepatic, 686.
Collodion, iodized, in erysipelas, 517.
Color-perception, 96.
Colotomy, 97, 541, 542.
Column of Goll, 478.
Coma, diabetic, 9; dyspeptic, 516.
Comma-bacillus, 240, 260, 381, 416, 436.
Compensation of physicians, law governing the, 626.
Concussion of the spine, 617, 634.
Congestion, cerebral, during mental work, 308.
Conjunctivitis, 482; purulent, 266.
Constipation, 431; ergot in, 37.
Consumption, prevalence of, at different ages of life, 527; when is the risk from, greatest? 36, 194, 235, 335.
Consumptives, North Carolina climate for, 364
Contagiousness, duration of, after acute infectious diseases, 573.
Contusions, decoction of valerian in, 598.
Convulsions, in children, 236, 543; of the tongue, 509; puerperal, 46, 576.
Cook County Hospital, 401.
Copper and cholera, 512.
Copper-colored spots on the forehead, 56.
Cord, umbilical, tying of, 166.
Cornea, local anæsthetic to the, 417; result of great loss of substance of, 389.
Corning, Dr. J. Leonard, book notice, 216.
Corns, cure for, 672.
Corpulence, book notice, 524.
Corrosive sublimate, 196; solutions, 168; tolerance of small doses of, 312.
Coryza, 13.
Cough, vapor of glycerine for, 403.
Country doctor, 464, 473.
Cowan, Dr. George, modification of Barnes' dilator, 529.
Crawcour, Dr. J. L., iodide of potassium, 584.
Cremation, 140, 571; in London, 28.
Cretinism, in adults, 302.
Crime and madness, 547.
Croom, Dr. J. Halliday, notice of book by, 20.
Crotalus, 718.
Crothers, Dr. T. D., acute impulsive inebriety, 289.
Croup, 357; calomel in, 36; diphtheritic, 580, 697; tracheotomy in, 643, 645, 665, 700.
Crudeli, Dr. Conrad Tommasi, address at the International Medical Congress, 197.
Cuirass, for Potts' disease, 13.
Cuming, Dr. James, address, British Medical Association, 1884, 169.
Curette, uterine, 578.
Cyr, Dr. Jules, book notice, 216.
Cysticercus in the vitreous, 703.
Cystitis, 545; intravesical injections for, 704; naphthaline in, 597.

D

DaCosta, Dr. J. M., notice of book by, 19.
Dacro-adenitis, 164.
Dana, Dr. C. L., concussion of the spine, 617.
Dana, Dr. S. W., delirium following the use of morphine, 64.
Dandruff, 376.
Daniell, Dr. Alfred, book notice, 244.
Davis, Dr. G. G., corrosive sublimate, 196.
Deafness, new apparatus for the relief of, 38; sudden, caused by mumps, 517; sudden, of supposed syphilitic origin, 257.
Death, 706; diagnosis of apparent, 293; sudden, in childbirth, 361.
Death-rate, of New York, 15.
Decapitation, does it cause instant death? 531.
Deformities, rachitic, of the lower extremities, 612.
Delirium following the use of morphine, 64.
Delirium tremens, paraldehyde in, 39.
Delusions, therapeutical, 379.
Dentistry, 43.
Dermatology at Vienna, 56.
Deutsch, Dr. Solomon, book notice, 299.
Diabetes, 231, 580, 600, 705; coma of, 9.
Diabetics, expired air of, and iodoform, 515.
Diaphragm, rupture of, 402.
Diarrhœa, 575; chronic, sea voyage in certain cases of, 512; naphthaline in, 597; nervous, 12; treatment of, 99.
Dickinson, Dr. D., ascites, 588.
Diet, infant, 14.
Digitalis, 191; physiological action of, 516.
Dignity, professional, 586.
Diphtheria, and croup, 697; calomel in, 36; experimental, 544; tracheotomy in, 700.
Diplomas of the United States Medical College, 249.
Disease, causes of, 169.
Disease germs, 451.
Dissection, the laws of, 486.
Doctor, in fiction, 182.
Doughty, Dr. S. W. H., cocaine in gynecology, 658.
Drinking-water, purification of, 236.
Drops, the weight of, 377.
Druggist and drug appraiser, 26.
Drugs, explosive, 599.
Dugas, Dr. Louis A., notice of death of, 468.
Dumm, Dr. S. C., plea for the country practitioner, 473.
Dupuytren's finger contraction, 276, 375.
Dwight, Dr. Francis M., hospital report, 264.
Dysentery, 223; homœopathic treatment of, 433; micrococci of, 404.
Dyspepsia, dietetic treatment of, 575; treated with hot water, 563.
Dyspnœa in Bright's disease, 681.
Dystocia, from cervical fibroids, 383.

E

Ear, diseases of, 3; external, 119, 173; influence of dental irritation on the, 107; practical observations on the human, 149; quacking sounds in, 139; ulcerations of, with anæsthesia of the trigeminus, 688.
Ears, pain in, due to irritation in the jaws, 374.
Earle, Dr. Charles W., cirrhosis of the pancreas, 505.
Ecchymosis, of nervous origin, 403.
Eczema, and trophic centres, 485.
Edson, Dr. Benjamin, morphia in cardiac disease, 401.
Edson, Dr. Cyrus A., new spray-producer, 306.
Education, of children with defective hearing, 675.
Effusion, pleuritic, 598.
Electricity, in elephantiasis, 598; in hydrarthrosis, 69; in treatment of pleuritic effusion, 476; the induced current in pleuritic effusions, 266; the therapeutical value of, 710.
Electrolysis, in stricture, 94, 195, 250; in treatment of uterine tumors, 329.
Elephantiasis, and electricity, 598; scroti, 629.
Ellingwood, Dr. Finley, tape-worm, 82.
Elliott, Dr. A. A., injury from a pitchfork, 429.
Emmet, Dr. T. A., notice of book by, 690.
Encephalitis, acute, of children, 696.
Endarteritis, ulcerative, 50.
Endocarditis, ulcerative, 554.
Enterotomy, 601.
Epery, Dr. F. W., 225.
Epilepsy, and apomorphia, 598; osmic acid in, 317; puerperal, 351; treatment, 213.
Epileptics, the pupils in, 39.
Epley, Dr. F. W., cancer of the pancreas, 532.
Epithelioma, of the auricle, 107.
Ergot, in constipation, 37.
Ether, acetic, 221; formic, 222; hydriodic, 221; hydrobromic, 221; hydrochloric, 221; inhalation of, 64.
Etherization, rectal, 224, 252, 326, 346.
Etiquette, breach of professional, 588.
Ethmoid, disease of, 106.
Evans, Dr. S. A., menstruation in animals, 588.
Extracts, fluid, 92.
Extra-uterine pregnancy, 224, 331.
Eye, artificial, 389; calomel in diseases of, 38; changes in, immediately after death, 163; dropping fluids into, 675; first enucleation of the, under cocaine, 713; tuberculosis of, 681.
Eyeball, staphylomatous, 93.

F

Fable, a medical, 587.
Faradization, in obstetric practice, 544.
Farcy, 107.
Feeding, infants, 351.
Feet, sweating of, 97.
Fever, chlorotic, 37; intermittent, excited by intestinal worms, 317; malarial, 327; malarial, morbid anatomy, 68; puerperal, 141; puerperal, cold baths in, 333; puerperal, in Denmark, 332; puerperal, prophylaxis in, 38; substitute for the cold bath in, 11; typhoid, 696; typhoid, and syphilis, 385; typhoid, grave nervous symptoms in, 517; typhoid, mild forms of, 404; typhoid, polyuria in convalescence, 265; typhoid, rational treatment of, 629; typhoid, rose-colored eruption not characteristic of, 707; typhoid, symptomatic treatment of, 597; typhoid, the apyretic form of, 97; typho-malarial, 327; typhus, 339; yellow, 7, 264; yellow, at Panama, 509; yellow, micro-organisms of, 168; yellow, the origin of, 435.
Fibroids, cervical, as a cause of dystocia, 383.
Fibro-sarcoma, naso-pharyngeal, 455, 469.
Fisk, Dr. Samuel Aug. Loomis, on Colorado climate, 526.

Fistula, in ano, 539.
Florida, as a health resort, 502; climate of, 83, 109, 280, 308.
Fœtus, gastric secretion in, 376.
Food for the febrile, 95.
Forceps, a new bullet, 419; in breech presentations, 308; the obstetric, in breech presentations, 607.
Forearm, rotation of, 599.
Formulary of unofficinal preparations, 21.
Foster, Dr. Joel, Obituary, 18.
Fothergill, Dr. J. Milner, affections of the heart, 1, 29, 57, 86.
Fowler, Dr. George B., a plea for the use of delicate tests for albumen in urine, 94; "The Hæmorrhoid Quack," 527.
Fowler, Dr. George R., neurectomy for removal of facial neuralgia, 368.
Fracture, of the acetabulum, 576; of the clavicle, 527.
Freckles, 432.
Free, Dr. Spencer M., hysteria in the male, 346.
French, Dr. C. H., maternal impression, 140.
Fresh air supply for cities, 560.
Fright, mental states induced by, 530.
Fuller, Dr. Fraser C., rattlesnake-poisoning, 137.
Fuller, Dr. S. E., pseudo-bulbar paralysis, 487.
Furuncle, 68.

G

Galentin, Dr. C. B., notice of book by, 299.
Galvanism, in tubal pregnancy, 337.
Gant, Dr. F. J., notice of book by, 20.
Gardiner, Dr. Henry K., 308.
Garrigues, Dr. H. J., tubal pregnancy, 446.
Gas, illuminating, poisoning by, 201.
Gastralgia, malarial, 288.
Gastritis, chronic, 540.
Gastrostomy, 95.
Gatchell, Dr. Edwin A., the North Carolina climate for consumptives, 364.
Geddings, Dr. W. H., indigenous leprosy, 177.
Gelsemium, in tetanus, 34.
Genu valgum, 276.
German Naturalists and Physicians, 696.
Giddings, Dr. W. P., 251.
Glioma of the retina, 163.
Glycerine, vapor of, 644; vapor of, for cough, 403.
Glycosuria, 230.
Goitre, present status concerning treatment, 602; removed by operation, 671.
Goldsmith, Dr. Middleton, cancer of the stomach and pancreas, 593.
Goll, column of, 478.
Gonorrhœa, 77, 600; potassa chlorate in, 272; stigmata maidis in, 280.
Goodwillie, Dr. D. H., a simple stomach-pump, 305.
Goodwin, Dr. Charles H., notice of book by, 692.
Greaves, Dr. Thomas, correspondence, 584.
Greely, Lieut., rescue of, 206.
Green, Dr. Edward H., medical history of Lady Franklin Bay expedition, 254.
Green, Dr. T. Henry, book notice, 300.
Groat, Dr. F. A., eczema, 485.
Gross memorial professorship, 239, 330.
Guarana, 491.
Gums, the lancing of children's, 615.

H

Hallucinations, bilateral, 108.
Hamamelis, Virginiana, 53.
Hamilton, Dr. Allan McLane, iron albuminate in anæmia, 140.
Hanks, Dr. H. T., notice of day-book by, 46.
Harlan, Dr. A. W., "dead teeth in jaws," 473.
Harris, Dr. R. B., veratrum of gelsemium in tetanus, 34.
Harris, Dr. M. L., diaphragmatic hernia, 401.
Harvey, as a student of nature, 718.

Panum, Dr. P. L., address at International Medical Congress, 203.
Paris Academy of Medicine, 51.
Park, Dr. G. C., extra-uterine pregnancy, 224.
Park, Dr. Roswell, electric otoscope, 616.
Parker, Dr. J. B., acute iodism, 587.
Parker, Willard, M.D., LL.D., in memoriam, 189.
Parker, Dr. William S., quacking sounds in the ear, 139.
Parker, Dr. W. Thornton, 181; tube for injecting and measuring the uterus, 305.
Parks, Dr. N. O. D., malarial gastralgia, 288.
Parmenter, Dr. John, local use of ether in the bladder, 25.
Partridge, Dr. Edward L., notice of translation by, 494.
Patella, fractured, 265.
Patellar tendon reflex, 11; and ankle clonus, 403.
Pathology, gastric, 630.
Paul, Dr. Constantine, notice of book by, 19.
Peck, Dr. Edward S., astringents and caustics in ophthalmic practice, 482.
Pelletierine, 81.
Penis, fracture of, 549.
Pension, psycho-pathology of application for, 140.
Pepsin, 272.
Peptones, 193.
Peptonized milk, 138.
Percy, Dr. Samuel R., cocaine, 550.
Perimeter, M. Hardy's, 389.
Perimetritis, 333.
Periostitis, rheumatismal, 598.
Periproctitis, simulating typhoid fever, 377.
Peritonitis, from diseases of the vermiform appendix, 600; tubercular, 47.
Perry, Dr. A. W., the abuse of tonics, 718.
Peters, Dr. John C., muriate of lime, 288; Warburg's tincture, 63.
Pharmacology, 663.
Philadelphia Hospital, 179.
Phlebitis and rheumatism, 12.
Phosphorus, action of, on the fœtus, 293; dosage of, 380.
Phthisis, death-rate of, 69; in the light of recent discoveries, 679; mullen-leaves in, 319; new remedy for, 9; old catarrhal, 699; transmissibility of, 193; treated by overfeeding, 66.
Phymosis, without operation, 599.
Physician, the oldest, in the State, 672.
Physicians, holiday seasons for, 348; visiting list, 692.
Physiology, address in, 113; every-day, 588; temperance, 42.
"Physyke" a good general rule, 27.
Pinkney, Dr. Howard, natural sulphur waters, 539.
Pitchfork, injury from, 429.
"Pidgen" English, 72.
Placenta, adherent, 27.
Placenta prævia, 89.
Plaster-of-Paris jackets, 428; substitutes for, 705.
Pleurisy, with effusion, electricity in, 476.
Pleuritic effusions, the induced current in, 266; exudations, the tuning-fork in the diagnosis of, 11.
Pleuro-pneumonia, 271.
Pneumonia, and cold bath, 543; acute, and tuberculosis, 430; acute lobar, 434; calomel in the treatment of, 683; chill in etiology of, 13; chronic, in the light of recent discoveries, 679; cocci of, and organisms of salivary septicæmia, 140; iodide of potassium in, 13; subacute, 304; subclavicular tympanitic resonance in, 266; tuberculous croupous, 399.
Pneumonotomy, 223.
Pneumotherapy, application to diseases of the heart, 124.
Podophyllum, poisoning by, 345.
Poison labels, 319.
Poisons, chemical, formed in the intestinal canal, 683.
Polk, Dr. W. M., cocaine as a local anæsthetic in gynecology, 489.
Polycoria, 164.
Polypi, nasal, 189.
Polypus, naso-pharyngeal, 387.
Polyuria in typhoid fever, 265.
Poore, Dr. Charles T., book notice, 356.
Post-mortem specimens, temporary preservation of, 560.
Potash, bichromate of, antiseptic properties of, 11.
Potassium, iodide of, 492, 584; in pneumonia, 13; in syphilitic deafness, 257; large doses, 688; large doses in syphilis, 641.
Potts' disease, 13.
Practitioners' Society of New York, 361, 413, 609.
Prayer, the therapeutic effect of, 713.
Pregnancy, and morphinism, 11; diagnosis of, 330; extra-uterine, 362; 383, 466, 577; false, 69; morphine in vomiting of, 237; multiple, 26; protracted, 584; tubal, 96, 445; tubal arrested by galvanism, 392; tubal, galvanism in, 337; vomiting of, 624, 664.
Prendergast, Dr. P. J., continuous suture, 616.
Prepuce, dilatation of, 599.
Presbyopia, and accommodation, 586.
Prostate, enlarged, 10, 293; hypertrophy, treated without catheterism, 22.
Pruritus, oleate of chloral for, 543.
Pseudarthrosis, 292.
Psoriasis, 431.
Pupils, the, in epileptics, 39.
Puerperal infection of the male, 707.
Purpura, cachectic, 264; varieties of, 517.
Pustule, malignant, 542.
Pyelitis, calculous, nephrectomy for, 569.
Pyelo-nephritis, 697.

Q

Quarantine, in cholera, 570.
Quebracho, alkaloids of, 599
Quinan, Dr. John R., notice of book by, 20.
Quinine, amorphous borate, 112; contra-indications in the use of, 66; hydrobromate of, 222; hypodermics of, in differential diagnosis, 265.

R

Rabies, 92; in birds, 96.
Rachitis, 139.
Rape, rights of defendant, 279.
Rattlesnake-poisoning, 137.
Rectum, a receptacle for excremental matter, 309; imperforate, 97, 541; malignant affections, operative treatment of, 274.
Redfern, Dr. Peter, address in physiology, 113.
Refraction, new method of determining, 388.
Reese, Dr. John J., book notice, 299.
Resorcin, antidote of, 683; for whooping-cough, 551; in laryngeal affections, 543.
Respiration, effect on, produced by compressed air, 122.
Respiratory medicaments, 122.
Reynolds, Dr. Walter B., poisoning by podophyllum, 345.
Rheumatism, and phlebitis, 12; carbolic acid in, 10; gonorrhœal, 229; manaca in, 31; ozone in, 601.
Rhinelander, the case of, 520.
Richmond, French compliment for, 27.
Rickets, 357.
Riley, Dr. F. C., failures with cocaine, 658.
Riley, Henry A., Esq., the laws of dissection, 486; the law regulating the compensation of physicians, 620.
Roane, Dr. James, veratrum viride, 586.
Roberts, Dr. F. T., book notice, 299.
Robbins, Dr. C. W., intravesical injections for cystitis, 704.
Rockwell, Dr. A. D., notice of book edited by, 300; the induction coil, 513, 558, 585; tubal pregnancy arrested by galvanism, 392
Rodenstein, Dr. L. A., 305.
Rogers, Dr. Robert E., obituary, 300.
Roosa, Dr. D. B. St. John, correspondence, 391; cocaine, 463.
Roosevelt hospital, 263.
Rose-cold, 420.
Rotation of the forearm, 599.
Rothacker, Dr. W. A., notice of book by, 692.
Rowe, Dr. Frank H., tape-worm, 56.
Royal College of Surgeons, 81.

S

Sarcoma, generalized, 431; of the mediastinum and lung, 441.
Saundby, Dr. Robert, examiners at the Royal College of Surgeons, England, 81.
Scabies, naphthol in, 403.
Sciatica, 265; treated by congelation, 347.
Sclerosis, following infectious diseases, 293; of the coronary arteries, 682.
Scrofula and tuberculosis, 376.
Scrotum, a compressor for, 529.
Scudder, Dr. H. Martyn, cholera in India, 255.
Sée, Professor Germain, respiratory medicaments, 122.
Seguin, Dr. E. C., notice of book by, 21.
Semple, Dr. Armand, notice of book by, 19.
Septicæmia, masked, 375; puerperal, 292.
Sero-sublimate, 548.
Serpent-poisoning, 408.
Sewers, ventilation of, 495.
Sexton, Dr. Samuel, dead teeth in the jaws, 525; defective hearing in the public schools, 675; diseases of the external ear, 3, 119, 149, 173, 374.
Shafer, Dr. J. P., renal calculi, 587.
Shawl-pin, swallowing of, 695.
Sheardown, Dr. T. W., the abuse of medical charity in the South, 109; the treatment of dyspepsia by hot water, 563.
Shears, Dr. C. H., cocaine in dentistry, 657.
Shillock, Dr. P. T., intestinal obstruction, 196.
Shirk, Dr. J. K., notice of book by, 46.
Shrady, Dr. George F., strangulated hernia, 591.
Siamese twins, 39.
Sickness, the cost of, 586.
Silver, iodide of, 644; nitrate, in adenitis, 375; nitrate of, injections of, in the bladder, 501.
Simon, Dr. W., book notice, 524.
Sizer, Dr. A. B. de S., congenital hemorrhoids, 584.
Skene, Dr. A. J. C., book notice, 356.
Skin, ethics of, 167; specific sensibility of the, 359; treatment of diseases of, at Vienna, 532.
Skull, osteitis of, 386.
Sleep, 706.
Small-pox, honey for, 293; susceptibility to, 181.
Smiley, Dr. D. B., correspondence, 448.
Smith, Dr. Andrew H., catheterization, 456; the tolerance of small doses of corrosive sublimate, 312.
Smith, Dr. Eugene, cocaine in indectomy,
Smith, Dr. F. W., the swallowing of a shawl-pin, 695.
658.
Smith, Dr. H. Lyle, tape-worm, 82.
Smythe, Dr. G. C., pelletierine for tape-worm, 81.
Smith, Dr. J. Lewis, peptonized milk, 80, 138.
Smith, Dr. Samuel W., plaster-of-Paris jackets, 428.
Snake-bites, 404.
Soda, bicarb., in tonsillitis, 153.
Sodium iodide instead of potassium iodide, 112
Sohlin, Dr. Charles, jequirity, 562.
Somnambulism, partial, 247.
Soul-blindness, 536.
Spermatophobia, 238.
Spermatorrhœa, 238.
Sperry, Dr. S. B., hay-fever in an infant, 503.
Spina-bifida, injections in, 292.
Spine, concussion of, 617, 634; disease and curvatures of, 701; prognosis of curvatures of the, 683.
Spiræa ulmaria, in enlarged prostate, 10.

Spitzka, Dr. E. C., anomaly of a vertebra, 680; gross anatomy of the fourth ventricle, 249; hippocampus *vs.* hypocampa, 335; morphological status of the cerebellum, 111; the anatomy of the lemniscus, 393, 421, 449, 477.
Spleen, extirpation of, 84, 166.
Splenectomy, 37.
Splints, flexed, 716.
Sponge, artificial, 9; Mr. Gamgee's, 108.
Sprains, 112.
Spray-producer, 306.
Squint, atropine in convergent, 389.
St. Catherine's Hospital Report, 402.
St. Luke's Hospital, medical histories of, 446.
Stammering, 601.
Stanton, Dr. John G., correspondence, 279; shall officers in the army engage in private practice? 83.
Sternberg, Dr. George M., book notice, 495; disease germs, 451; pneumonia cocci and organisms of salivary septicæmia, 140.
Stevens, Dr. B. N., correspondence, 448.
Stewart, Dr. Jacob H., obituary, 300.
Stickler, Dr. J. W., cocaine in general surgery, 657; sea-voyage and chronic diarrhœa, 512; traumatic tetanus, 288.
Stimson, Dr. Lewis A., laparomyotomy, 370.
Stockard, Dr. C. C., fibro-cyst of the uterus, 177.
Stomach, cancer of, 385, 469, 593, 686; dilatation of, 431; dilatation of, in children, 489; gun-shot wound of, 224; irrigation of, 540; miliary aneurisms of, 97, 293; pathology of, 630; swashing sound in, as a symptom, 264.
Stomach-pump, 395.
Stomach-tube, death from the introduction of, 504.
Stone, Dr. R. M., glass wound, 456; gun-shot wound of the stomach, 224.
Strabismus, latent, 389.
Stramonium, leaves of, for painful joint affections, 316.
Streeter, Dr. F. B., 420.
Streeter, Dr. H. W., electrolysis in stricture, 94, 250.
Stricture, urethral, 673; treated by massage, 96; electrolysis in, 94, 250.
Strictures, of the œsophagus, 278, 543.
Sugar as a food, 139; bismuth-test for, 491.
Summer complaint, 87.
Summer vacations, 16.
Supra-renal capsule, 545.
Surgeons, army, shall they practise outside of their posts? 83.
Surgery, pulmonary, 641.
Surgical aid to children, 373.
Surgical Society of Paris, 165, 386.
Suture, continuous, 616.
Symptoms, value of certain, in diagnosis of diseases of children, 67.
Syphilide, acute phagedenic pustular, 441.
Syphilis and cholera, 385; and mercury and cholera, 447; bacillus of, 687; inherited, affections of the liver in, 544; initial sclerosis, excision of, 360; treatment by inunction, 360.

T

Tabes, migraine in, 597.
Tait, Dr. Lawson, 643.
Tape-worm, 56, 81, 232, 251, 308; treated with chloroform, 112, 429, 475, 601.
Tattoo-marks, removal of, 598.
Tauszky, Dr. Rudolph, correspondence, 418.
Taylor, Dr. W. H., rectal etherization, 346.
Teeth, dead, in the jaws, 379, 444, 473, 521, 525, 564, 659; loosening of, 432.
Teller, Dr. S., fracture of the clavicle, 527.
Tendon, reflex, patellar, 11.
Testicles, supernumerary, 196.
Test-papers, urinary, 140.
Tetanus, 34; following Heaton's method for the cure of hernia, 64; infantum, 631; traumatic, 288.
Thallin, 687.
Thayer, Dr. C. C., hepatic albuminuria, 124.
Theine, 491.
Therapeutical Society of Paris, 53, 386.
Therapeutics, artificial hypnotism in, 632; dogmatic, 588; heat and cold in, 397, 413; medicinal and non-medicinal, 579.
Thermometry, aural, 489.
Therpyline, hydrate of, 545.
Things to try, 420.
Thompson, Dr. John H., chloroform and tape-worm, 601.
Thorax, funnel-shaped, 39.
Throat, an instrument for pencilling children's, 377; typhoid ulcerations of the, 405.
Thumb, dislocation of the first phalanx, 578.
Thymol, in treatment of cholera, 296.
Thyroid gland, function of, 266; removal of, 375.
Tibia, ununited fracture, 205.
Toe-nail, ingrowing, 96.
Tongue, convulsions of, 509; gummy tumor of, 403.
Tonics, the abuse of, 718.
Tonsils, hypertrophied, 598; the three, 365; their structure and function, 415; tuberculosis of, 292.
Tonsillitis, 153.
Tonsillitome, Marconi's, 616.
Tonsillotomy, 597.
Tosswill, Dr. Louis H., notice of book by, 20.
Tooth, death following extraction of, 97; replantation of, 84.
Tracheotomy, in croup and diphtheria, 534, 643, 645, 665, 700.
Trachoma, in the negro, 704.
Trance, 706.
Transfusion, 572.
Transplantation, without pedicle, 161.
Trichinosis, 140.
Trichorrhexis nodosa, 683.
Trineural fasciculus, 450.
Traumatism and tuberculosis, 376.
Tubercle bacilli in the non-tuberculous, 138.
Tubercles, of the breast, 39.
Tuberculosis, 302, 317; and acute pneumonia, 430; and joint disease, 578; and traumatism, 376; and scrofula, 376; general, 189; miliary in the light of recent discoveries, 679; of the eye, 681.
Tumor, bony, of the brain, 707; gummy, of the tongue, 403.
Tumors, removal of benign, 139.
Tuning-fork, in the diagnosis of pleuritic exudations, 11.
Tyson, Dr. James, chronic parenchymatous nephritis, 179.

U

Uhler, Dr. J. R., cocaine in general surgery, 657.
Ulcer, of the leg, 681.
Ulna, luxation of, with Colles' fracture, 279.
Unchastity, 531.
Ureter, closure of, 52.
Urethra, stricture of, treated by massage, 96.
Uræmia, 246; and urea, 698;
Urea, 69.
Urethritis, gonorrhœal, 673.
Urine, albuminose or peptone in, 350; ammoniacal, 12; detection of morphinism by examination of, 685; disturbance of, in nervous diseases, 375; mercury in, 405.
Uterus, anteflexion of, 693; cancerous affections of, 265; fibro-cyst of, 177, 470; inversion of, 382; latero-positions of, 332; tube for measuring, 305.

V

Vaccination, 173; insusceptibility to, 663; susceptibility to, 181.
Valentine, Dr. Samuel M., notice of death of, 436.
Valerian, decoction, in contusions, 598.
Valvulitis, cardiac, 29.
Variola and varicella, 707.
Venesection, in puerperal convulsions, 576.
Veratria, in muscular tremors, 272.
Veratrum viride as a prophylactic against peritonitis after surgical operations, 586; in tetanus, 34.
Vermiform appendix, peritonitis from, 600.
Vidal, Dr. Etienne C., correspondence, 474.
Vinegar, in post-partum hemorrhage, 66.
Vision, cerebral centres for, 342; improved by hyperbolic lenses, 163.
Vitreous, cysticercus in, 703; removal of foreign bodies from, 164.
Vivisection, 46.
Vomiting, in children, 38; in pregnancy, 624.

W

Wackerhagen, Dr. G., a new needle, 419.
Wallian, Dr. Samuel S., oxygen as a remedial agent, 283, 313.
Warburg's tincture, 63.
Ward, Dr. E. B., 415.
Warts, 432.
Water, hot, therapeutical effects on nervous diseases, 471.
Waters, natural sulphur, 539.
Weber, Dr. Leonard, nervous origin of some disorders of the alimentary canal, 481, 497.
Webster, Dr. David, enucleation of a staphylomatous eyeball, 93.
Weigert's method of staining the brain and spinal cord, 628.
Weisse, Dr. Faneuil D., pain, in stricture after gonorrhœal urethritis, 673.
Weld, Dr. G. W., cocaine in dentistry, 657.
Wendt, Dr. E. C., cholera and bacterioscopy, 589; chronic pneumonia and phthisis in the light of recent discoveries, 679; tuberculosis and acute pneumonia, 430.
Whiskey, as an anæsthetic, 588.
White, Dr. Leonard D., 448.
Whitla, Dr. William, notice of book by, 46.
Whooping-cough, resorcin for, 551.
Wilfert, Dr. H., tape-worm, 82.
Wilder, Dr. Burt G., the morphological status of the cerebellum, 249.
Williamson, Dr. C. H., yellow fever at Panama, 509.
Wilson, Dr. F. M., cocaine in minor surgery, 582.
Winters, Dr. Joseph E., tracheotomy in diphtheritic croup, 645, 665.
Wise, Dr. A. T. Tucker, book notice, 494.
Woakes, Dr. Edward, notice of book by, 19.
Woodward, J. J., M.D., obituary, 215, 243.
Wound, abdominal, 415.
Wounds, antiseptic treatment of, 357.
Wylie, Dr. W. Gill, vomiting in pregnancy, 624.
Wyman, Dr. Hal C., stramonium leaves for painful joint affections, 316.

Y

Yellow fever, the alleged "vaccine" against, 712.
Yeo, Dr. Gerald F., notice of manual by, 495.

Z

Zenner, Dr. Philip, cerebral localization, 232, 342, 458, 536; the centres for vision, 146.
Ziegler, Dr. Ernest, notice of book by, 692.
